The General Practitioner of Times Gone By.—Before and behind his saddle were strapped the instruments and medicines the doctor might want, for he never knew what was before him. There were no specialists in Drumtochty, so this man had to do everything as best he could and as quickly. He was chest doctor and doctor for every other organ as well; he was accoucheur and surgeon; he was oculist and aurist; he was dentist and chloroformist, besides being chemist and druggist. It was often told how he was far up Glen Urtach when the feeders of the threshing-mill caught young Burnbrae, and how he only stopped to change horses at his house and galloped all the way to Burnbrae and flung himself off his horse and amputated the arm and saved the lad's life. "You would hae thocht that every meenut was an hour," said Jamie Soutar, who had been at the threshing, "an' a'll never forget the puir lad lying as white as deith on the floor o' the loft wi' his head on a sheaf, an' Burnbrae haudin' the bandage ticht an' prayin' a' the while, and the mither greetin' in the corner. 'Will he never come?' she cries, an' a' heard the soond o' the horse's feet on the road a mile awa in the frosty air. 'The Lord be praised!' said Burnbrae, and a' slippit doon the ladder as the doctor came skelpin' intae the close, the foam fleein' frae his horse's mouth. 'Whar is he?' was a' that passed his lips, an' in five meenuts he had him on the feedin' board and wes at his wark—sic wark, neeburs—but he did it weel. An' ae thing a' thocht rael thochtful o' him; he first sent aff the laddie's mither tae get a bed ready. 'Noo that's feenished, and his constitution 'ill dae the rest,' and he carried the lad doon the ladder in his arms like a bairn, and laid him in his bed, and waits aside him till he wes sleepin', and then says he: 'Burnbrae, yir a gey lad never tae say, "Collie, will ye lick?"' for a' hevna tasted meat for sixteen hoors.' It was mighty tae see him come intae the yaird that day, neeburs: the verra look o' him wes victory."—IAN MACLAREN, in "A Doctor of the Old School."

A Condensed Code Dating from the Fourteenth Century.—Guy de Chauliac, a French surgeon, author, and teacher, was both chaplain and physician-in-chief for Urban V. and two other popes of Avignon. He was educated at the universities of Bologna and Montpellier and practised a long while at Lyons. He was born about 1300. He taught the following code of ethics: "Bold when sure. Cautious in danger. Kind to the weak and sick. Friendly with fellow-workers. Constant in duty. Not greedy of gain."

WHEN SHALL WE OPERATE FOR APPENDICITIS? ¹

BY WILLY MEYER, M.D.,

ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS.

SOME time ago a colleague while reading a paper on appendicitis excused himself for again treating a subject that had been discussed so often in our societies and considered in our journals within recent years. Not long afterward I heard another colleague say that "he was absolutely convinced that ere long this craze of the laity to be operated upon for appendicitis would cease; far fewer operations would soon," he thought, "be performed for this reason."

If anything could induce me to read a paper on appendicitis, these remarks of well-known gentlemen would. In this particular instance they are not the cause. This paper was ready, in part at least, last winter. For special reasons I felt myself unable to finish it.

In my estimation we doctors cannot discuss this subject too often. If the laity should actually sooner or later give up this craze for operation, the doctors only are responsible for it.

Now, I am not of the opinion that we should in our medical societies still discuss the pathological-anatomical aspect of appendicitis. Most exhaustive treatises, that deal also with this chapter of the disease, have appeared here and abroad within the last years. Nor do I believe it to be of special value to give a synopsis of all the cases operated upon by the single man, to give "personal statistics" before a gathering of general practitioners. At our time, when almost every moderately busy surgeon has operated for appendicitis on more than one hundred or one hundred and fifty patients—and I can conscientiously state that I also have done this—at this time, I say, conclusions based upon personal experience must be drawn, and these on a broad basis. We have to consider not only the immediate danger of the acute attack of appendicitis which happens to confront us, but also the patient's future life. If anywhere there exists a necessity for a prognosis "quoad completam valetudinem," it is here.

Viewing the subject of appendicitis in this light, everything necessarily concentrates around the question: "When shall we operate for appendicitis?"

It was a great misfortune, I believe, for those who were stricken by appendicitis within late years that the "early operation," originally advised by Dr. McBurney, had to give place by virtue of medical evolution to the so-called "timely operation."

Generally speaking, no doubt it is more scientific in the treatment of patients to individualize, thus also in appendicitis; it is more scientific not to find the indication for the removal of the appendix given as soon as the diagnosis of its inflammation has been made. And I for my part am convinced that the

medical profession will continue to carefully weigh the pros and cons with reference to operation in each case of appendicitis. Yet at the same time I am firmly convinced that if we could give one hundred equally serious or equally light cases of appendicitis to two equally trained surgeons, the one who believes in and always does an early operation will save a greater percentage of lives than the other who only takes the knife in hand during the attack when he considers it to be time. Thus we can well understand that a number of surgeons take the stand to-day that appendicitis is a surgical disease and always requires an operation as early as possible. I think, in spite of all the able talking and writing by these competent surgeons, the general practitioner will never yield to this demand. He sees too many cases of appendicitis getting well without an operation, for the time being at least. He therefore clamors for individualizing, and wants, if possible, distinct symptoms when an operation is indicated, when he has to call in the surgeon.

Now, Mr. President and gentlemen, let me say right here, that I, with many other medical men, believe it to be the general practitioner's duty in every case of appendicitis to call in a surgeon at once. Not that I mean to say that the surgeon is needed for consultation to verify the "diagnosis" of the given case. Nay; only let the patient be seen and carefully examined by physician *and* surgeon. Let the surgeon, who naturally sees more severe cases of appendicitis, at least add his advice as to what would best be done in the case to that of the physician; let the surgeon also be aware that he may be called upon at any moment, day or night, to operate, provided the indication for operative interference is not given at once.

For convenience' sake I shall divide inflammation of the appendix into three classes:

1. Acute perforative (gangrenous) appendicitis—appendicitis acutissima.
2. Acute appendicitis.
3. Subacute and chronic relapsing appendicitis.

This division is feasible from the clinical standpoint.

1.

If anywhere a physician through undue temporizing can do irremediable harm to his client, it is in the first class. I am well aware that the diagnosis of acute sepsis starting from a defective appendix is sometimes extremely difficult; that not so very rarely the primary profound sepsis is so marked, that the true character of the disease is never recognized. Well! These patients will die with or without an operation. But if a doctor attends a patient who suddenly develops a more or less pronounced chill with quick, continued rise of pulse and of temperature, mainly of the former, after having had for a short while or formerly annoying sensations in the appendix region, this chill must be for the general practitioner the signal for an immediate call for surgical help.¹ Not always a chill

¹ A distinct chill accompanying the other well-known symptoms always indicates here the sudden invasion of formerly healthy parts by infectious material: a perforation. If adhesions had previously been formed, a localized periappendicular abscess will develop. If the appendix was perfectly free in the abdominal cavity, general diffuse suppurative peritonitis must ensue.

¹ Read before the Metropolitan Medical Society, December 23, 1895.

introduces these acute symptoms. But if it does, slight or severe, it is of great pathognomonic value. Do not allow yourselves, gentlemen, to be deceived at this early time of the serious disease by the patient's general good feeling. The latter often has nothing whatever to complain of, did not and does not vomit, has appetite, feels when questioned "very well." But the rapidly rising pulse above 120, the quick respiration, the high and increasing temperature, more or less pain on pressure in the appendix region over Douglas' sac—by vaginal or rectal palpation, also over the left side of the abdomen, especially in the left lumbar region, showing the involvement of the entire sac—and all these symptoms after a sudden onset, will properly direct the experienced. Quick work is needed here. Not hours, minutes count. I know very well, Mr. President and gentlemen, that the immediate shock of the sudden blood-poisoning may be so marked that the surgeon hesitates to add that of the operation. I am also well aware that a few patients who have had a distinct perforative appendicitis got well without an operation, or were successfully operated upon after a while, when nature had formed adhesions around the original large effusion. Six years ago I assisted a colleague in opening an intra-abdominal abscess in the linea alba of a boy of six years, who a short while before had voided a large amount of pus through the rectum. According to the history of the case, this surely had originally been a diffuse purulent exudation due to perforative appendicitis. In 1891 I operated on an athletic young man of eighteen, who four days previous had been suddenly stricken down with symptoms of a most acute peritonitis. He was taken home in a wild delirium. For three days and nights it required the steady watch of a number of attendants to keep him in bed. On the fourth day I was called in by the attending physician, and when I opened the abdomen, the incision, made in the loin, evacuated a large abscess with the gangrenous appendix and two fecal concretions. On gentle palpation the finger could feel the anterior and posterior surfaces of the liver, and enter between the coils of the intestines in many directions. The patient recovered. A similar third case was successfully operated upon by me last January. Of course, under proper treatment and care these patients get well. But the course of their disease has been exceptionally fortunate. Perhaps five out of a hundred have such luck. But exceptions cannot and shall not guide us in drawing our conclusions. It is a fact that patients with acute perforative appendicitis generally die if not operated upon in the very first hours. Dr. McBurney saved fourteen out of twenty-four patients.¹ In my hands, three out of four of the patients operated upon within the first twelve hours after the perforation have recovered. Those operated upon later, five in number, died. This is not the place to give a history of these most interesting cases. I shall publish them at the proper time. Only one I should like to mention very briefly, a case which, I believe, shows beyond doubt that the clinical symptoms of a true perforative appendicitis can rapidly develop without a macroscopical defect in the walls of the vermiform. The case is embodied in those four operated upon within the first twelve hours that I have just mentioned. On the eve of January 12th of this year I was called by our president, Dr. S. Marx, to see with him at once a young lady, who had since 4 P.M. developed symptoms of most acute peritonitis, evidently due to a perforation of the appendix. Patient had complained of occasional pain and discomfort in the right groin for eight days. For safety's sake the doctor very wisely had kept her in-doors under proper directions. There had been no fever at any time,

¹ N. Y. MEDICAL RECORD, March 30, 1895.

pulse never above 84. Suddenly a chill of moderate severity and short duration set in on the afternoon of the eighth day. The doctor saw her at four. Pulse, 120; temperature, 103.1° F.; respiration, 30. Slight tenderness on deep pressure in the appendix region. Two hours later the pulse was 126–132; temperature, 104° F.; respiration, 36. When I arrived at the patient's house at about 7:30 the pulse had gone up to 144; temperature was above 104° F.; respiration same as before. In addition to the former symptoms, Douglas' cul de sac was sensitive on rectal palpation. There was no nausea nor vomiting, and the patient's subjective condition was good. I could but confirm the doctor's diagnosis: perforative appendicitis. After consultation with the family, we agreed to operate at 9 P.M. Meanwhile Dr. Bull had been asked for a consultation by the request of the family. The doctor agreed with our diagnosis and the proposed operation.¹ The latter was performed by me at once. The appendix showed acute catarrhal inflammation, no gangrene, no perforation. There was no fecal concretion, not the slightest adhesion. Neighboring parietal and visceral peritoneum was highly hyperemic and in the small pelvis some thin sero-purulent fluid. Free drainage to all sides, wound left open with secondary sutures in place. After a short improvement, patient was between life and death with symptoms of acute sepsis for five days. With the help of most careful attention she pulled through. Temperature and pulse had been normal for some time, when on the twentieth day after the operation, fever and pains in the region of the left kidney set in. The urine, which lately had been slightly turbid, suddenly cleared up. We diagnosed obstruction of the ureter by pus and clotted blood, due to perforation of an abscess in one of the pyramids of the kidney into its pelvis, a diagnosis in which Dr. A. Jacobi, who had seen the patient with us a number of times, concurred. That this really was the case could soon be demonstrated. Under strong diuretic treatment the passage from the left kidney to the bladder was suddenly cleared. The urine showed a very heavy, bloody, purulent deposit. All symptoms now at once improved. Analysis of the urine corroborated our diagnosis, proving beyond doubt that an abscess within the left kidney, caused most probably by embolism of streptococci at the time of the onset of the acute sepsis, had spontaneously perforated. Three weeks later the urine was normal. The patient recovered.

This case proves that acute sepsis with general peritonitis can set in in cases of acute appendicitis without any macroscopical lesion, all other clinical symptoms of perforation being present.²

If I may still add one or two remarks they are these:

If patients recover from an operation for perforative

¹ The ideal aim of operative surgery would, of course, be to prevent such an occurrence by the early distinct diagnosis of an approaching acute appendicitis of a serious character and the early removal of the organ, based upon this diagnosis. But shall we ever get so far in making our diagnosis? And if we should, may we hope that all those concerned will consent to the operation at such a time?

² That we really had to deal in this case with acute septic peritonitis, due to acute inflammation of the appendix with passage of infectious micro-organisms (bacterium coli commune, etc.) through its (macroscopically) unbroken walls, was proved to me by the inflamed condition of the appendix and its immediate neighborhood at the time of the operation. 2. The presence of thin, turbid, sero-purulent fluid in the small pelvis, besides the other clinical symptoms. 3. The slight lull in the symptoms after the removal of the appendix, the original focus of the disease thus having been eliminated. 4. The serious, almost fatal sickness, with a pulse running up to 160, under symptoms of acute sepsis for five to six days. 5. The perforation of an intrarenal abscess twenty days after the operation, temperature and pulse going up again when the abscess cavity had been put under pressure by the obstruction of the ureter. 6. The analysis of the turbid material that came down from the left kidney, showing many varieties of pyogenic micro-organisms, no tubercle bacilli.

appendicitis with acute general suppurative peritonitis, we must not always expect a speedy recovery. The favorable condition of such a patient within the first three days after the operation does not permit us to prognosticate continuous recovery as in so many other cases of laparotomy. Convalescence often is slow and protracted.

Further, the age of the patient seems to me to be very important with reference to the prognosis. Patients in the prime of life have the best chance, as in other diseases. Recovery from this disease in patients who have not yet reached puberty is rare.

II.

If generally it is not difficult to answer the question, When shall we operate? in cases showing the clinical symptoms of acute perforative (gangrenous) appendicitis, this is quite different in the ordinary acute attack of appendicitis. All the former symptoms are present, only in a lesser degree. We have at first clearly a localized peritonitis before us. Will these symptoms increase, will they suddenly take a more serious, a fatal aspect? Nobody can answer these questions with a fair degree of probability. No doctor, not the most experienced, can give even a fairly reliable prognosis. The disease is too varying in its symptoms; the virulence of the infecting micro-organisms, principally that of the bacterium coli commune, too different; the pathological-anatomical picture as we can study it during the operation too kaleidoscopic. I have long ceased attempting to make a prognosis in the given case; have long ceased also to state before the operation that we shall find an intra- or extra-appendicular abscess, a faecal concretion, or a stricture within the appendix, etc. Of course, it sharpens the surgeon's diagnostic capabilities to construct a pathological-anatomical picture before the operation and then to compare this diagnosis, though silently made, with the actual condition. I too do this in every case. But nothing is more fallacious. We therefore have to be candid and confess: we are unable, at present at least, and will, I fear, be unable forever, to diagnose the actual lesion of the appendix with reference to its clinical severity in the beginning of an acute attack of appendicitis, especially in the beginning of the first attack. We can only diagnose "acute appendicitis." We thus are also not able to give a reliable prognosis. No doubt this sounds queer. Ordinarily we expect a greater ability of the individual man in giving a strict diagnosis and prognosis with increasing experience. And yet, I believe, just the contrary is the case in appendicitis.¹ We must therefore look out for symptoms which can guide us in determining: Here the work of the physician ends, and here that of the surgeon commences. In former years I never felt more embarrassed than when called upon by a colleague to see with him a case of acute appendicitis in its early stage. I said to myself: If you temporize and suddenly more serious symptoms develop, which in spite of an operation prove fatal, colleague and relatives will perhaps say: "He waited too long." And if you advise and perform the operation at once and the patient should die, the family may say: "He was too quick in using the knife, recovery might have taken place if he had waited." The experience of years has stopped my embarrassment. Well can I understand, however, the position of those who always operate at once. There is not much thinking, no worrying. They come, they act, provided there is still time for help. Very often I was tempted to follow these col-

leagues. Yet, as mentioned above, this way of procedure is not really scientific. It also does not always mean that we do the best for the patient, though we have done the safest. The safest must not necessarily be the best.

I now follow, I fancy with many of my colleagues, a certain distinct plan of observation in trying to determine when the time for the operation has come. Of course, I know that distinct rules to properly guide us here cannot be given. The same symptoms which may have prompted us in one case not yet to advise the operation—the patient's recovery without surgical active interference bearing out the wisdom of our procedure—may prove fatal in the next. Yet by clinging to a certain routine observation with reference to the patient's pulse, less with reference to the temperature, I believe we can in the majority of cases of acute appendicitis be able to perform a "timely operation."

I should say: If all the symptoms of appendicitis are well developed and the pulse has a tendency to go up above 116–118, still more if it goes above 120 and stays there, the indication for the operation is given.¹ The fever has very little value. This is a recognized fact to-day. The incongruity between pulse rate (high) and temperature (low) even gives the case a more dangerous aspect and should always call for quick work. Now and then other specially marked symptoms will let us urge the operation. Thus I have observed that continuous extreme sensitiveness to the touch over the appendix region should give the indication for operation in spite of comparatively low temperature and pulse. In these cases I found a stricture near the tip of a long appendix and its lower extremity blown up, giving the whole vermiform a pear-shaped appearance. In a number of instances we have a certain apprehension, induced partially by increasing experience, partially perhaps by the patient's irregular pulse, or his specially sick appearance, or his indifference, or his pale face and hollow eyes, although the pulse does not press us. Here too, we operate. But for the majority of cases of acute appendicitis I believe the above rule, if strictly adhered to, will generally enable us to be still on time.

But in order to be "on time" the patient must be carefully observed. After physician and surgeon have seen the patient, a nurse must stay at the bedside and take pulse and temperature from hour to hour, day and night. People who can afford it should always give in and call for a nurse at once. Poor patients should be sent to the hospital. If we do this as soon as the diagnosis has been established, we have done the best for the patient. It goes without saying that in observing these cases the use of opiates is absolutely excluded.

Unfortunately there will always be a number of cases of acute appendicitis where even under this régime the operation, in order to be a timely one, will be done too late. In spite of it the patient dies. Therefore, if the attack is sharp, the pulse rising, and if we are in doubt what is best to be done, let us operate rather than wait, even in large cities like New York, where we can always be on hand on short notice.

The country practitioner, who cannot see his patient so often, will save more lives by always having his patients with an acute attack of appendicitis operated upon as soon as possible.

A few remarks here, before I proceed, with reference to the so-called "first attack." It would, no doubt, be very wrong to believe that the first attack of inflammation really is the first pathological symp-

¹ The differential diagnosis between acute appendicitis and other diseases does not belong to the scope of this paper. I naturally had to let my reasoning rest on the basis of an undoubted attack of inflammation of the vermiform.

¹ It has seemed to me that at this height every additional beat of the heart is of great clinical importance. Thus I would consider in a patient with a pulse of 122 the operation far more pressing than in a case with pulse of 118, the doctor always carefully counting the whole minute.

tom which befalls the appendix. "First explosion" would better express, it seems to me, the actual occurrence. We all know that the faecal concretions so often found in the appendix, do not form over night; a stricture which shuts off upwardly an abscess within the tip of the organ sometimes found on cutting open an appendix which was removed during the first inflammation, does not develop within a few days. Thus it is clear that explosive material slowly accumulates within the lumen of the appendix, that important changes slowly set in within the different structures of its wall, also often of the nourishing vessels in its mesenterium. At last it comes to a climax: the conflagration—inflammation—breaks out. And can we diagnose these premonitory symptoms? In a number of instances, I trust, we are able to do so, especially in children, more easily if they have had an attack of appendicitis before. Little girls, for instance, may complain that the belt of their skirts presses and hurts them on the right side, that on buttoning their shoes the pressure of the right thigh against the abdomen causes pain. Or the appetite suddenly changes: formerly favorite dishes are suddenly disliked; others, never taken before, are relished. Defecation may become irregular. Now and then reflex symptoms, especially, it seemed to me, neuralgia in the region of the heart, with irregularity of the pulse may set in. Of course, it is extremely difficult, almost risky, to explain such vague symptoms as an approaching inflammation of the appendix. But if children do complain of such symptoms, the family physician should at least think of a probably threatening inflammation of the vermiform and should never omit to carefully palpate the region of the appendix. If it is found to be sensitive to the touch, a proper regulation of diet and defecation then ordered and strictly adhered to, may still avert the inflammation or defer its appearance. And if the doctor on careful examination cannot find anything wrong in the region of the appendix, also not posteriorly to the ascending colon, where, just in the instances referred to, the appendix so often is found during a subsequent operation, let him then at least be still more on his guard, if really after a shorter or longer period an acute appendicitis sets in. Just these cases, it seemed to me, may prove fatal on account of acute or subacute gangrene and perforation. Here the most careful observation of the patient, especially of the pulse, is imperative; here an "early" operative interference generally is necessary and may save the patient's life.

One case only out of a great many in my experience let me relate to you, to show that even in younger patients, in children, whose heart responds so much more quickly to an infection, the above given rule, "look out for the pulse," holds good in order to determine the time for the operation. In September of this year I was called by a colleague to see a girl of almost ten years of age, the only daughter of well-to-do parents. Patient had been taken sick with vomiting and abdominal pains two days previously. A laxative given by the mother produced no relief, so the family physician was sent for. He diagnosed appendicitis. It was the patient's first attack. When I saw the girl with him in the middle of the third day of the disease I found: abdomen soft and flat everywhere: ability to pass wind and urine; some pain on deep pressure in the appendix region: temperature, 101.8° F.: pulse, 108; face, pale. After careful consideration of the symptoms present we told the mother that we would call together again in the evening. If the symptoms were on the increase, especially if the pulse went up toward 120, we intended to operate the same night. A nurse was sent for at once. We met at 9 P.M. and found the temperature 103.2° F.: pulse, 122. I sent for my assistants and ordered everything prepared for

the operation. Meanwhile the father had called in another surgeon for consultation, a gentleman for whom I have the highest regard, who is known to be a most conscientious doctor, with abundant experience. After careful examination of the patient he did not favor an immediate operation, and gave the prognosis that by the next morning all symptoms would be found improved. I yielded reluctantly, not without having given vent to my opinion that I considered in this case waiting more dangerous than the operation. The next morning all symptoms were found to be improved. Temperature, 100° F.: pulse, 96. Noon: temperature, 99.8° F.: pulse, 90. We ventured to give the parents hope that this attack might pass without necessitating an operation. Suddenly, in the afternoon at about 3:30, without any warning a slight chill set in. Half an hour later, temperature 103.6° F.; pulse, 132. One hour later, temperature 104.6° F.; pulse the same. Meanwhile I had been sent for. I was busy with an operation, but notified my assistants. When everything was ready for the operation it was almost 8 P.M., temperature then 103.6° F.; pulse, 132. The operation showed the appendix in a markedly catarrhal inflammation; there was no perforation but its tip was adherent between the coils of the intestines; the parietal peritoneum was slightly injected, and there was some murky serous fluid in the small pelvis. Removal of the appendix was quickly performed and the wound drained. The beneficial effect of the operation on pulse and temperature lasted only about twelve hours. Then everything began to increase again. Black copious vomiting, so often found in cases of septic peritonitis of this kind, set in. In spite of everything that human efforts could accomplish the girl died thirty hours after the operation and thirty-five hours after the chill, viz., the beginning sepsis.

Is such a case not apt to make us think? Should it not induce us to let certain symptoms, if present in a case of acute appendicitis, always force the knife into our hands, even in children, or rather especially in children, whose heart, as mentioned above, has so much less power of resisting a septic infection? And if once our diagnosis, based on good symptoms, should really have been wrong and we should remove an appendix which is healthy—certainly an extremely rare occurrence, perhaps never to come—has such a terrible crime been committed, provided the patient recovers? I maintain: in cases of doubt the operation is generally safer than waiting, provided the patient is still in the early days of the attack. If the physician finds it proper not to call in the surgeon at once, but owing to the continuance of rather severe symptoms does so on the fourth, fifth, or sixth day of the attack, it may be extremely difficult for the surgeon to know what is best to advise. It seems to me that in this stage of the disease a number of patients will be saved under palliative treatment who would die if then operated upon.

All these later remarks, Mr. President and gentlemen, refer to the very first days of the first attack of an acute appendicitis. In the later stages of an acute attack which is on the decline the decision generally is much easier for the surgeon. Suppose that we had resolved to temporize and that the first immediate danger had passed. The pulse, rather high before, slowly drops. What have we to expect, say, on the fourth, fifth, or sixth day of the disease, or still later on? The answer is not difficult. The acute inflammation either continues to subside or an abscess forms. The diagnosis of the latter is easy. As soon as pus is suspected it must be evacuated.

III.

But if a severe inflammation has passed without leaving any serious marks in its course, or if it has

been rather mild all the time of the actual disease, "subacute," as we say, should the patient then, well as he may appear, be considered a healthy person and discharged cured? I decidedly say: "No." I hold that an appendix which has been inflamed once, seriously or mildly, must be looked upon as being a diseased organ which is most apt again to give cause for serious trouble at any time in the future. I therefore say, and let me emphasize this as the central point of my paper: *An appendix which has been inflamed once should always be removed after the first attack.* This is best done at the time when the patient has fully recovered from the effects of the disease, say from four to six or twelve weeks after the onset of the inflammation. How long a period may elapse before the next attack occurs of course no doctor can state with any degree of accuracy.

With hospital patients recently I have waited from about one or two weeks only after the subsidence of the inflammatory symptoms. These patients want to go home as soon as they feel well. If they once leave the hospital they will not call for help again before the next attack has set in. And that next attack may prove fatal. Formerly the indication for the removal of the appendix in this class of cases was considered to have come when repeated attacks had run the patient down or had prevented him from enjoying his life.

If a short term for the removal of the appendix after the first attack should be wanted, this operation—in contrast with the "early operation" and the "timely operation"—might perhaps with propriety be called "the prophylactic operation" for appendicitis. If physician, patients, or relatives do not accept the advice to have the appendix removed after the first attack, I urgently emphasize that the operation should be done in the beginning of the second attack, provided it occurs and proves to be of a rather serious character; and if the patient should be fortunate enough to pass even the second attack without any operation, then not to wait still longer to remove the organ. When two attacks have occurred, the third is bound to come. It can be expected so much the sooner the shorter the interval between the former attacks has been. Then at least, gentlemen, do not wait with your advice to have an operation until that next attack sets in. The explosion may later come so suddenly that the patient is at once beyond the reach of surgical help.

The following sad cases out of a number of similar ones in my experience may serve for illustration—the one showing how the first recurrence, although not severe in the beginning, may suddenly become serious and prove fatal; the other emphasizing the fallacy of believing that after, say, two or three attacks mild in character the next must also run a subacute course.

CASE I.—A girl of almost nine years of age had had a slight attack of appendicitis when five years old. Under palliative treatment she was all right after three days. Three years later she was again suddenly stricken down with vomiting, pain in the region of the appendix, fever, and corresponding pulse. On the night of the first day the pulse had reached 120, but dropped to 84 the next morning. The next days were passed in comparative comfort. On the evening of the fourth day a slight dulness could be made out on gentle percussion above Poupart's ligament; the abdomen was flat, soft, and nowhere else painful to the touch; micturition and defecation were undisturbed, as before; temperature, 101.4° F.; pulse, 96. A beginning abscess was diagnosed and a surgeon called in for immediate operation. When he came four hours later the situation had suddenly changed. Temperature had jumped to 104° F., without a previous chill; pulse to 144; the general sub-

jective condition was undisturbed. The surgeon confirmed the presence of an abscess. To guard against the threatening perforation into the general peritoneal cavity, the operation was performed without delay. The appendix, friable and adherent to the parietal peritoneum, was found to be blown up in its lower portion to a bulb of about a walnut's size and contained a dark brown, purulent fluid of fetid odor. The long upper portion of the organ, corresponding to about two-thirds of its length, made a sharp curve in about the middle; near the entrance into the cecum a faecal concretion was impacted. The surrounding peritoneum appeared to be normal; it was only very little injected. The operation was difficult, but had been carried out with great care and skill. The wound, packed, was left open. Inside of two hours the temperature had gone down to 100.4° F., but soon it began to rise again. The pulse never dropped below 120; fifteen hours after the operation the little girl died under the symptoms of acute sepsis.

CASE II.—A girl of twelve years was seen by me in consultation on September 9th of this year. She had just been moved from the country into the city on account of an acute attack of appendicitis, the third within six months. Pulse and temperature were on the decrease during the last twelve hours. I therefore did not favor an immediate operation, but seriously emphasized the absolute necessity for the removal of the appendix within the next two to four weeks. The doctor, who had called me in, fully coincided with this advice. Soon afterward the girl again seemed well and was up and about. The old family physician now took charge of the family's welfare for the winter. When informed of what had happened and of the proposed operation, he was of a different opinion, as was also a prominent surgeon who examined the patient with him. They did not find the indication for the removal of the appendix, as the girl had then nothing to complain of. Suddenly, seven weeks after I had seen this child, the girl, when in school, was seized by violent abdominal pains, etc., followed by profound shock. As soon as possible she was now operated upon. The appendix was perforated. She died.

I know that the question has yet to be decided: Is an appendix really a diseased organ after one attack of inflammation, is it such a constant menace to the life of the possessor that the urgent advice of its removal after one attack of inflammation is justified? I for myself am fully satisfied that this is the case. I firmly believe that such a patient continually walks on a volcano; that Damocles' sword hangs over him so long as the appendix is in his belly. This is true so much the more if some time after the attack deep pressure in the region of the vermiform still causes a more or less painful sensation. The answer to this question rests with the general practitioner. It is, in my opinion, the duty of the family physician to carefully follow up these patients in order to determine "how many" actually remain well after one attack of appendicitis. I am convinced that, had we statistics on this important point—and we do not have them yet—not twenty per cent., not ten per cent. of them will be found to remain healthy. And if twenty per cent. actually should remain well forever and eighty per cent. get a second and third attack and so on, does that not count? Are we able to determine who will be the fortunate twenty out of the given hundred cases? And can they not be stricken down more seriously for the second or third time in a place and amid surroundings where good surgical help at the proper time cannot be brought to them—on an ocean trip, in the mountains, on a railway car? Cannot the following attack start so seriously that the patient is at once beyond the reach of surgery?

The surgeon who removes the appendix after one

attack of inflammation should, in order to do his share in clearing up this question, publish the pathological-anatomical condition of the organ. Since February of this year I have thus operated four times. Case I. A boy of ten showed an abscess in the tip of a very long appendix. A tight stricture separated it from the upper portion of the organ. Case II. A girl of twenty had an ulceration in the end of the appendix. Case III. A man of twenty-two had a very long appendix and a very narrow mesenterium. The organ was twice curved, like a worm. At this curve there were commencing strictures. Case IV. A lady of twenty-six showed the vermiform embedded in adhesions and bent in its middle at a sharp angle of about thirty degrees. The point of the angle was drawn down posteriorly. Such lesions will not always be found after one attack, especially not in the so-called catarrhal inflammation. But one of the following attacks may produce them.

I know it is not easy to induce a seemingly healthy person, say of seventeen years, to gather sufficient courage to submit to an operation. I know it requires the firm conviction of the doctor that he is doing the best for his client to advise the parents of a child which has successfully pulled through a serious sickness a short while ago to have that child operated upon. I know it requires absolute confidence in the doctor for the parents to give their consent to the operation at such a time. "Not two out of ten will follow your advice," said a well-known surgeon to me a few months ago, when I told him what I was going to fight for in cases of appendicitis as long as I live. I am, Mr. President and gentlemen, of a different opinion. I am sure the time will come when the question, "When shall we operate for appendicitis?" will be solved by adopting the advice of those colleagues who always operate at once in the beginning of the first inflammation of the appendix, or else will be looked upon in the light just explained. Profession and laity must be educated to this end. I believe almost that the public will sooner listen to such advice than will the majority of general practitioners. And yet, even if he be of a different opinion personally, I deem it the solemn duty of the family physician to present the facts clearly to the family. Let the patients, the parents, the relatives decide.

It is not a proper objection, which many of you may also make, that sometimes six, eight, ten years or more may elapse before a second attack sets in. The objection might be of some little weight if the intervening time were spent in perfect health. But this happens only rarely. Last winter I had to operate for perforative appendicitis with general diffuse suppurative peritonitis upon a patient who had had the first attack twenty-five years ago. The appendix was of the size of a thumb and more than six inches long. There was free pus in the peritoneal cavity. An intra-appendicular abscess in the tip of the organ, held in by a tight old stricture, had perforated at last. She died thirty hours after the operation. Had this lady enjoyed perfect health during this quarter of a century? By no means. She had been ailing intermittently, had for years been treated for dyspepsia, had within the last three years led a miserable life on account of repeated attacks of abdominal pains. Her doctor's advice to have an operation performed was, nevertheless, always rejected by her. Now is it not worse at the end to have, for instance, a mother of twenty-seven years of age, who had her first attack of appendicitis, say, as a girl of seventeen, torn away from husband and children in her second attack than to have given the patient and relatives the worry and probable trouble of an operation soon after the first inflammation? Should not the parents rather stand the worry, to have, say, their little girl of five years

operated upon than perhaps later have to take leave from her forever?

There is only one single point seemingly weak in the chain of proofs in favor of the stand I and I trust many colleagues have taken, or at least soon will take, with reference to the question, "When shall we operate for appendicitis?" That is, we cannot *guarantee* that the patient will recover from the operation. The statistics of Bull, it is true, show us that the operation in the hands of experienced surgeons is almost void of danger. Yet there is almost two per cent. of deaths. My own patients, twenty in number, have all recovered.

But can we guarantee recovery in any other intra-abdominal operation? Does not the general practitioner send patients with reducible hernia to the hospital for operation almost every day? And do we not perform almost every day the radical operation for this trouble, in many cases bilaterally, right away? Is the removal of the appendix after the first attack a more serious operation than the radical operation for hernia? I think not. The patient afflicted with hernia has the inconvenience of wearing a truss. His rupture may suddenly become irreducible or strangulated. The appendix once inflamed may suddenly perforate, no doubt a much more serious accident than the incarceration of a hernia. It is to be regretted that patients who have once passed appendicitis have not to inconvenience themselves by also wearing a truss or similar apparatus. I believe the question, "When shall we operate for appendicitis?" could be much sooner solved.

Now, Mr. President and gentlemen, one of you might ask me with propriety: If you take the stand that every patient who has once passed an attack of appendicitis should have his vermiform removed, why do you not rather join the ranks of those who believe in immediate operative work as soon as the inflammation has commenced? Why do you eventually jeopardize the patient's life by adhering to the principle of the "timely operation?" Is that done only in order to work scientifically, to individualize?

To this query I should answer:

1. The operation is safer in its result if we have not to work in acutely inflamed tissues.
2. If we work in acutely inflamed tissues we are often forced to drain.
3. This drainage may in spite of secondary suture produce or leave a tendency to the appearance of a ventral hernia.

If on the other hand we operate after the first attack, we not only will find the appendix more or less without any adhesions or held down by slight ones only, we not only can close by stitches the entire wound in its main structures—peritoneum, muscles, and fascia, and thus provide against ventral hernia. Nay, we almost can guarantee to the patient that, if he recovers, he will not get a ventral hernia. On the great importance of this point I need not dwell. That alone should induce the attending physician earnestly to advise his client to have the appendix extirpated before the probable next attack. We owe this progress also to Dr. McBurney. As known by you, last year he recommended applying the principle of the blunt separation of the abdominal muscles according to the direction of their fibres¹ also to the operation for appendicitis performed in the quiescent stage.² The operation is a most excellent one. Its technique is a little more difficult than that of the usual oblique or longitudinal incision. The entrance into the peritoneal cavity is rather narrow; it runs transversely.

¹ Von Hacker, Witzel: "Gastrostomy;" Albert: "Colostomy."

² "The Incision Made in the Abdominal Wall in Cases of Appendicitis, with a Description of a New Method of Operating." *Annals of Surgery*, 1894, vol. xx., p. 38.

It is applicable in cases only where the appendix is not confined by too-far-reaching adhesions, a point which of course can be made out only during the operation. It is obvious that after one attack the adhesions are less than if more than one has taken place.

I have operated according to this plan within this year seven times, even in very robust men. In two cases only had I to add the usual incision, this on account of far-reaching adhesions. All patients recovered, so far without a ventral hernia. In five cases in which the plan of the operation could be carried out and the abdominal wall closed by suturing layer by layer, the result is ideal. The skin is perfectly movable over the fascia. The right side of the abdomen has the same strength and tonus as the left side, since no nerves had to be divided. The operation has left no mark except the scar. I am sure this result will be permanent. Just think what that means for a child whose life lies before it; what it means for a young man who has to live on the income of his daily bodily work; what it means for an unmarried young woman, who will sooner or later marry and become pregnant.

Thus you see, Mr. President and gentlemen, many surgeons try to improve the result of the operation for appendicitis by perfecting its technique, by selecting the proper time for the same. Work hand in hand with your surgical brethren. Do not think, as many yet do, that the surgeon intends to invade a domain that formerly belonged to you alone, but try with us to further clear up and improve the treatment of this terribly treacherous disease.

Summing up, I would say:

1. In cases of diffuse perforative appendicitis the operation must always be done at once. Patients have the best chance to recover if operated upon within the first twelve hours. Exceptionally patients get well without an operation.

2. In cases of acute appendicitis the patients always need careful observation. If the pulse goes up above 116 to 120 and has the tendency to stay there, the indication for an operation is given.

In case of doubt, the operation is better than waiting.

3. In cases of subacute (mild) attack of appendicitis, also after the first severe attack from which the patient recovers without immediate operation, the appendix should be removed. The appendix, once inflamed, has to be looked upon as a diseased organ which is very apt to give repeated and more serious, even fatal trouble in the future.

When done at this time, we can almost always perform the blunt division of the abdominal muscles according to the direction of their fibres and thus save the patient the probable appearance of a ventral hernia.

Warm.—

Press me closer, all my own;
 Warms my heart for thee alone.
 Every nerve responsive thrills,
 Each caress my being fills;
 Rest and peace in vain I crave,
 In ecstasy I live, thy slave;
 Dower'd with hope, with promise blest,
 Thou dost reign upon my breast;
 Closer still, for I am thine;
 Burns my heart, for thou art mine;
 Thou the message, I the wire,
 I the furnace, thou the fire;
 I the servant, thou the master—
 Roaring, red-hot mustard plaster.

—BOB BURDETTE.

Chilblains.—Dr. George J. Monroe writes, in the *Medical Summary*, that, after suffering tortures from chilblains, he obtained perfect relief by an application of acetate of zinc solution, $\mathfrak{z}$ i. to the pint of water.

BLOOD-LETTING AND PNEUMONIA.¹

BY ALFRED MERCER, M.D.

MR. PRESIDENT AND FELLOWS OF THE ACADEMY: The unprecedented activity of the medical mind during the last quarter of a century has largely revolutionized medical thought. During this brief period both theory and practice have undergone many changes, and in this connection may we not say that traditional medicine has been thrown to the dogs, and if Dr. Holmes were living he might add, "All the better for mankind, and all the worse for the dogs."

We have been loaded down with new remedies by the score or hundred, the merits of which a lifetime of observation would be altogether too short to test. Among the shifting scenes of the period antipyretics have had a brief hour of unwonted popularity, both for good and for evil, but for good conservatively.

We are pushing sanitary measures of prevention and we are searching for remedies to destroy the microbes of disease and their poisonous secretions without injury to the living body. To this end, just now animal extracts and attenuated animal poisons are on the crested wave of popularity as immunizing and antidotal agents, with flattering testimonials to their credit. Scanning the results of the period it will be found that

Surgery has Accomplished Marvels.—We can hardly say this of practical medicine. Therapeutical power to change, to cut short the course of disease, has by no means kept pace with our increasing knowledge. In practical medicine our gain in life saving has been in the direction of prevention, rather than in the use of any new or more scientific use of old or new remedies.

But it is not of the recent swinging of the medical pendulum that I wish to speak, but of the pendulum that scarcely moved to the right or to the left for more than a thousand years, "the lost art"—blood-letting.

It is a sad commentary we would make on the folly of human wisdom, on the acuteness of human understanding, in tracing cause to effect and effect to cause, as illustrated in the therapeutical history of blood-letting. The belief in the utility of blood-letting for the relief of disease has been entertained from remote antiquity down to near the middle of the present century with scarce a dissenting voice. Were these many generations deceived in their observations, doing mischief rather than good? Has the type of disease changed? Has physiology or pathology given us new light? Have new remedies been introduced, that the lancet is now thrown away, is thrown away forever?

Diseases come and go and change their type in cycles, from benign to malignant, and from malignant to benign, as observed in diphtheria, scarlet fever, and other affections; the benign requiring little or no treatment, the malignant being death-dealing from the beginning—change in type requiring change in treatment.

We believe the morbid condition, the essential pathology we call inflammation, is now, as it ever has been and is almost constantly, present, somewhere and in some form, in disease—constitutional symptoms giving expression to its type, and on a broad scale blood-letting was the former remedy for inflammation.

We will take pneumonia as a type of inflammation. Antimony, veratrum viride, aconite, cold to the chest, and digitalis are the remedies chiefly relied upon as substitutes for venesection. They are all arterial sedatives except digitalis, but act on different principles from blood-letting for the relief of disease. But

¹ Read before the Syracuse Academy of Medicine, January 7, 1896.

antimony is almost as obsolete as blood-letting. By orders from the surgeon-general of the United States army its use was prohibited during the war of the Rebellion. Yet we believe it to be a valuable remedy in chest affections.

There is still a long list of remedies in use, or plans of treatment for pneumonia. They are so numerous and so various that one might question which, if any of them, have any particular influence in promoting recovery.¹

During the greater part of the first half of the present century blood-letting was a daily matter of routine practice. I was educated in this school to a limited extent.

Fifty years ago Eberle's "Practice" was the popular text-book of the period. Professor Spencer, of Geneva Medical College, followed Eberle very closely in his lectures, and Eberle made free use of the lancet. Under certain restrictions and conditions he bled in tonsillitis, hysteria, and rheumatism, to say nothing about blood-letting in the more serious diseases affecting the three great cavities, head, chest, and abdomen. Still blood-letting was not altogether indiscriminately used. The fever—we had no clinical thermometer then—the character of the pulse, and the general condition of the patient were the guides for the use of the lancet.

But blood-letting was so common that to bleed in acute disease seemed to be the rule, not to bleed the exception. It was fashionable, and the laity often asked for it in health to ward off disease. Persons, more particularly of full habit, made annual or more frequent visits to the doctor's office to be bled, and claimed they were the better for the bleeding. Is there not a plethoric condition of the blood, as to quality or quantity, as well as an anæmic condition, the cause of morbid feelings without actual disease amenable to treatment, which blood-letting relieves, giving a better feeling of health and activity?

Pregnant women were often bled, for no other reason than that they were pregnant. It was the rule to bleed in almost all cases of injury, especially when some of the internal organs were thought to be injured, to ward off anticipated inflammation.

Blood-letting was not confined to the profession. Within the memory of those living the "barber surgeon" used the lancet at his pleasure.

Vix medicatrix nature was in the background. Active treatment was resorted to for the relief of trifling, self-limited disease, and do we not unnecessarily medicate this class of diseases to-day—seeming medication may be necessary for the moral effect—and claim credit for our science and skill that belongs to nature and the time required for the subsidence of the disease?

In the early years of the century the doctor had a lot of work to do with his lancet, blisters, emetics, and cathartics. These were his reliable forces, and he was diligent in their use.

In the palmy days of blood-letting the profession held it to be the remedy *par excellence* for inflammation. Professor Gross in 1862 wrote:

"General bleeding may justly be regarded as standing at the very head of the list of the constitutional remedies for inflammation, as it is at once the most speedy and the most efficient means of relief."

¹ There is a sedative saline treatment, and the following remedies are in use, some one or more of them being relied on as the chief means of treatment: the coal-tar antipyretics, guarded with camphor or caffeine; sedative and stimulating expectorants, salts of ammonia, the salicylates, opium, strychnine, mercurials, iodide of potassium, iron, quinine, chloral, chloroform, amyl nitrite, oxygen, cups, leeches, blisters, poultices, a cotton and oil-silk jacket, and now serum treatment is likely to come to the front. British Medical Journal, November 9, 1895. American Journal of the Medical Sciences, January, 1896, p. 85.

Again he says:

"Bleeding is no longer fashionable, the operation is denounced by every one. . . . If we formerly bled too frequently, too copiously, and too indiscriminately, it is equally certain, at least to my mind, that the operation is not often enough resorted to at the present day."

The profession entertained the belief that blood-letting relieved pain, reduced temperature, lessened the force and slowed the action of the heart; that it removed, in the days of humoral pathology, morbid matter from the blood, the product of inflammation; that, resorted to early in the congestive stage, it might arrest or abort inflammation; that when established it tended to check its extension, to promote absorption and resolution, and thus to shorten its duration.

Nearly all this was denied by the opponents of venesection. They contended that it did not remove any morbid agent from the blood; that it did not lessen the blood in the inflamed part; that it impoverished the blood in its powers of repair, lowered general vitality, and increased the hazards and delayed convalescence.

Cause of the Change.—But what caused this change in the use of the lancet? Several writers eminent in the profession have expressed the opinion that the change grew out of reaction from its excessive use and abuse, but they offer no facts or circumstance beyond this statement for the opinion.

It would seem that in the decade of the thirties experimental observations were instituted in some of the European hospitals for testing the value of different modes of treating pneumonia, some being treated by blood-letting, some with antimony, some by rest and diet alone.¹ Dr. Dietl thus treated 380 cases of primary pneumonia in the Charity Hospital of Vienna: 85 by venesection, with 17 deaths or 20.4 per cent., or one death in 5 cases; 106 were treated by large doses of antimony, with 22 deaths or 20.7 per cent.; and 189 were treated by rest and diet alone, with 14 deaths or 7.4 per cent., or 1 death to 13.5 cases.

In Fleischmann's Homœopathic Hospital, Vienna, at the same period, in 538 cases reported there were 28 deaths or 5 per cent., or 1 death in 17 cases. Upon their face these were startling figures, if half true, and with a conscientious profession must certainly have called for a halt to permit a careful review and study of the then methods of treatment.²

While we know something of the fallacies of statistics and of the many circumstances that modify the outcome of disease, we have no data by which we can analyze or criticise the above statistics, but as an offset we may say that in 12,271 cases of pneumonia treated in the British army there were 413 deaths, 1 death in 29 cases, or 3.5 per cent. In the navy, in 3,099 cases with 136 deaths, 1 death in 29 cases, or 4 per cent.³ On the South American station there was only 1 death in 59 cases. These figures come down to us from the era of blood-letting. Age and general health were in favor of the army and navy statistics, compared with the general run of patients admitted to hospitals.

The reported results of these experimental investigations no doubt directed the thoughts of the profession at large to a possible change in the treatment of pneumonia for the better and naturally would have raised the question of blood-letting in other diseases. We might also speculate that the infinitesimal dosing of Hahnemannism, in its purity, before these fraudulent, degenerate days, being followed by recoveries

¹ J. H. Bennett's "Lectures on Medicine," p. 292. W. Wood, 1859.

² J. V. Stimpson, M.D., "Homœopathy, its Tenets and Tendencies," Lindsay & Blakiston, 1854, p. 117.

³ Stimpson, p. 125.

from very serious acute ailments, led the profession to trust nature more and drugs less in the treatment of disease.

These observations were having their influence during the thirties and forties, gradually changing the drift of opinion, but the change in practice more rapidly developed during the fifties and by the dawn of the sixties blood-letting was practically obsolete. The medical journals discussed the blood-letting problem from time to time. Professor Stimpson, of Edinburgh, published a volume in 1854 under the title, "Homœopathy, Its Tenets and Tendencies," which soon after brought forth a reply from Professor Henderson, of Edinburgh, under the title of "Homœopathy Fairly Represented." These books discussed the blood-letting question and analyzed and sifted many statistics.

In 1856 or 1857 Dr. John Hughes Bennett, also of Edinburgh, published "Clinical Lectures on the Principles and Practice of Medicine," using the statistics referred to as the basis of the innovation he had already made in practice, with illustrative cases of pneumonia treated successfully by the use of antimony without blood-letting. A little later Sir John Forbes, of London, issued a small volume, "Nature and Art in Disease," in which he made the remark, somewhat sensational at the time, in relation to the practice of medicine, "It must mend or end."

In this country, in 1859, Dr. Jacob Bigelow, of Boston, put forth a little volume, "Nature in Disease." The tendency of all this literature was to check the heroic treatment of disease as practised in the first half of the century.

Still further in this country other influences were at work besides this literature to modify and change public and professional opinion. The Thomsonian doctors of the times, though not numerous, were aggressive, noisy, and boisterous, denouncing the regular profession at the street corners and in public places, decrying against blood-letting, mercury, arsenic, and quinine. They called themselves doctors and were called doctors. Practically there was no law in force regulating the practice of medicine at the time, and with many people one doctor's opinion was just as good as another's.

Homœopathy had just made its appearance, and was picked up for the most part by half-educated men attempting to practise medicine, and by superannuated clergymen, who joined in the hue and cry against the regular profession, however, in a more modest and less boisterous way. Their medication was also very modest compared with that of the Thomsonians, with their cayenne pepper, hot drops, lobelia, and teas by the quart or gallon.

To that portion of the public who naturally look elsewhere than to the regular profession for their medical advice, the contrast—each used to the same end, the restoration of health—between the easily taken sugar pellets and the disagreeable Thomsonian draughts was too great for the latter practice to last long. It gradually died out during the fifties. If any of its fraternity survived they assumed the name of botanic doctor or drifted into the eclectic fold.

Under these many influences blood-letting became unpopular, and for thirty or forty years has substantially disappeared from practice, so that the present generation of doctors know very little about blood-letting. I venture the opinion that not one-third of the profession of to-day have ever used the lancet or even seen it used. Although our text-books to date suggest or recommend its use to a limited extent, the suggestion is rarely if ever put into practice, and I suspect the authors who write, write more from the records of the past than from their own personal experience.

Perhaps the beneficial effects of blood-letting are best seen in the contraction of the blood-vessels and disappearance of the red and inflamed conjunctiva by the application of a leech or two to the temples. If general blood-letting will do for inflammation of internal organs what we can see leeches and cups do for an inflamed eye, there certainly is virtue in blood-letting. Nature herself every now and then furnishes us with an example of its utility, when hemorrhage from the nose relieves a throbbing and congested brain.

We used to hear of hemorrhage as a critical discharge in the progress of disease, and hemorrhage from accidental wounds has often relieved morbid conditions.

Certain principles and facts are pretty well established to serve as guides in the use of the lancet. From a blood-letting standpoint, children, the aged, and the feeble are known to be poor subjects for blood-letting. With them conditions seldom if ever arise to justify the use of the lancet; its use is largely confined to those of middle age and to the early stage of disease.

Pain, fever, and pulse were the chief guides for the use of the lancet, but more particularly the condition of the circulation, the action of the heart, the wiry feel and the incompressibility of the arteries. The pulse was studied much more critically and thoughtfully as to therapeutics and prognosis in former days than at the present time. Since we have had the clinical thermometer we have been disposed to study temperature and antipyretics to the neglect of other conditions and indications.

Now what are the successive steps in the development of inflammation? Generally, first a chill, followed by reaction of fever, pain, and excited arterial action. Locally we have congestion, stasis of blood in the part, with dilated capillaries; just how long this stage lasts in individual cases or in general we do not know, but sooner or later the blood corpuscles, serum, or lymph escape from the blood-vessels into the connective tissue and inflammation is established. In this congestive formative stage, at some time during the first twenty-four or sixty hours after the chill, is the stage for successful blood-letting, before exudation can have taken place to any great extent. Is it not possible that venesection at this early stage may abort or prevent the development of the inflammation? Was not this the case with those so-called pleuritic attacks of former days—chill, fever, sharp pain in the side, and short breath—when a single bleeding relieved all the symptoms and cut short the disease?

But what does blood-letting do?

It lessens the volume of blood, relieves the heart and lungs of a certain amount of labor, allays nervous irritability, slows and calms the excited, irritable heart, so that it contracts more deliberately, and thus the blood flows smoothly and placidly through the arteries and is thrown with less force into the inflamed part. Dr. Fothergill says it lowers the temperature.¹ Professor Loomis says it "has no influence on the temperature,"² and argues strongly against its use. We have bled so little since we have had a clinical thermometer that we have no personal experience to offer, but to the touch bleeding would seem to moderate fever. We have seen hemorrhage from the bowels in typhoid fever reduce temperature below the normal—to our sorrow.

We feel disposed to refer again to hospital statistics of a later date as to the results of the treatment of pneumonia by present methods.

In the Pennsylvania Hospital, Philadelphia, during the years 1845, 1846, and 1847, the deaths from pneumonia and pleuropneumonia were 6.25 per cent., or

¹ Fothergill's "Handbook of Treatment," p. 97.

² Pepper's "System of Medicine," vol. iii., p. 346.

1 death in 16 cases. During the years 1865, 1866, and 1867, the deaths were 18.50 per cent., or 1 death to 5.4 cases. In the years 1884, 1885, and 1886, the deaths were 31 per cent., or 1 death in 3.2 cases.¹

Dr. C. W. Townsend and Dr. A. Coolidge, Jr., of Boston, have compiled from the records of the Massachusetts General Hospital the percentage of the mortality from pneumonia from 1829 to 1889, the death rate starting in at 10 per cent., 1 death in 10 cases, and increasing gradually but somewhat irregularly up to 28 per cent., or 1 death in 3.4 cases in the sixty years. Before 1850 the treatment was heroic, from 1850 to 1860 transitory, after 1860 expectant. They claim that this increase of mortality comes more from the character of the patients as to age, habits, inebriety, and nationality—the disease being more fatal with foreign born—than from any change in the plan of treatment.²

We can hardly accept this as a satisfactory explanation for the increased mortality. It may be a factor in the increase, but we should look quite as much to change in treatment and to a possible change to a more malignant type of the disease. From the bad habits and impaired vitality of many hospital patients we should naturally look for a higher rate of mortality than in private practice. It would seem to me that the disease is more fatal now than during the early years of my medical experience, under the régime of blood-letting. Blood-letting could scarcely make matters worse, as is shown by results of other treatment in the hospitals of Boston and Philadelphia.

Four hundred and eighty-two physicians in Great Britain in 1884 treated variously in private practice 1,065 cases of pneumonia with a loss of 192 patients, a death rate of 18.2 per cent., or 1 death in every 5.5 cases.³

During the last five years there were 598 deaths from pneumonia in Syracuse, practically 120 deaths per year. We get excited over less than half this mortality from diphtheria or scarlet fever. To the extent that pneumonia is infectious it is preventable. Consumption stands first and pneumonia second in the list of causes of death in our city.

At the above proportion of causes to deaths, we had 3,289 cases of pneumonia in our city during the five years, constantly disabling about fifty persons during the whole period. We cannot believe the disease prevailed to this extent. We have no home statistics of private practice to compare with those of Great Britain, but from very limited observations we are of the opinion that our mortality might be double that reported from there—one death to every two or three cases, or from thirty to forty per cent.

We might quote other statistics of pneumonia: a digitalis treatment, with a loss of one case in fifty, or two per cent.;⁴ a strychnine treatment, with a loss of one case in fifteen, or six per cent.⁵ In thus gathering statistics we find them very conflicting and confusing. We hardly know what to think of such records. It must be a very different type of pneumonia from that we see in Syracuse, or there is a life-saving power in remedies that we have never dreamed of. If we could get such results from digitalis we would not say another word about blood-letting. We should be happy and content to let well-enough alone, believing that death from pneumonia could come only to the feeble and aged.

But blood-letting is not so obsolete in the books, even up to date, as it would seem to be in practice. Professor Walsh in speaking of pneumonia says:

"In the first place venesection has been numerically proven to diminish mortality and lessen the mean duration of the disease, and also to curtail the duration of its prominent symptoms, both subjective and objective; the pain in the side, the febrile action, the peculiar expectoration, and the physical signs."⁶

Prof. Francis Delafield writes in Pepper's "American Text-book of the Theory and Practice of Medicine," vol. ii., page 555:

"For the exudative inflammation of the lungs the plans of treatment most frequently adopted are: Venesection employed once or repeated several times, the quantity of blood taken to be considerable. This plan is not often employed at the present time."

Bartholow and Hare in their works on therapeutics advocate the use of the lancet. Articles in journals and in recent books might be quoted to the same end.

The most recent pathological thought is by no means antagonistic to blood-letting. Dr. John C. Warren in his recent work on "Surgical Pathology," page 132, says:

"After the stage of capillary stasis is reached arterial sedatives can only do harm, and blood should now be removed from the venous side of the circulation. The best results are obtained by bleeding from one of the principal veins leading from the inflamed focus. When bleeding is impossible leeching or wet cups should be resorted to. In this way the vessels are not only emptied, lessening the pressure, but an aspiration is also invoked which increases the rapidity of the flow, and this flow, as it is unaccompanied by increased pressure, sweeps away the leucocytes and removes the excess of oxygen, and thus lessens migrations; it also helps absorption of the exposed lymph."

But of the harm that blood-letting may do, or rather of the harm that it does not do, Prof. Austin Flint in 1879 wrote:

"Blood-letting impoverishes the blood and therefore impairs the vital powers. That the risk of harm in this direction has been of late years much exaggerated is certain, in view of past experience."

Prof. William Osler, Pepper's "American Text-book of Medicine," vol. ii., page 209, says:

"I have known a man to lose over ten pounds of blood in one week from gastric ulcer without succumbing."

After thus referring to the great loss of blood, he says:

"It is surprising to find how rapidly the regenerative processes go on, the normal amount being regenerated sometimes in a week or ten days after the hemorrhage, if it occur in a previously healthy individual. The lowering of the arterial pressure permits the absorption of the lymph from the perivascular spaces in the tissues, even while the hemorrhage is still going on."

We always aim for bloodless surgery but we frequently encounter free hemorrhage, with little or no harm to the patient. In the lying-in chamber we often have hemorrhage equal to a copious bleeding and the menstrual flow often equals a moderate bleeding, with no evil results.

To illustrate to what extent blood-letting may be carried with benefit for the relief of the lungs, I will briefly quote a case from Chelius' "Surgery," vol. i., page 440:

A chaise shaft, with tng iron attached, was thrust through the chest from left to right, passing under the sternum, projecting several inches on the right side. As difficult breathing came on soon after the accident, the patient was bled to the extent of four pounds with relief to the respiration. During the next nine days he was bled on five different occasions for urgent dysp-

nœa as it developed, with loss of six pounds more of blood, and still had vital and reparative power left to make a good recovery."

Personally I can call to mind no regrets for the use of the lancet, but there are occasions I do regret that I did not use it, and I have often heard like expressions from other practitioners who used the lancet in the early days of their practice. I once bled for well-developed tonsillitis. The patient was intelligent, of middle age and full habit. I argued that it would do his tonsillitis no good but himself no particular harm. "Well, then," he said, "I will be bled if you will bleed me; I have been bled before and it always did me good." I was rather glad to make the experiment, and to be sure that he had the full benefit of blood-letting for tonsillitis I bled him to faintness, but, as I expected, it had no influence over the course of the disease.

I feel disposed to report a case from an old notebook under the date of September 3, 1853:

P. S.—, a middle-aged, well-developed man, sustained crushing pressure of the chest by being caught against the door-jams of the roundhouse by an entering engine, fracturing one or more ribs on each side of the chest. The shock and depression were extreme.

Treatment.—Warm fomentations to the chest.

I find no notes till September 6th, 10 P.M., three days after the injury.

Reaction fully established, high fever, strong, full pulse and labored respiration; bleeding to twenty-four ounces with prompt relief to respiration.

September 7th, 10 P.M. Pulse not so strong and full as last evening, but respiration much more labored; cyanotic; incipient asphyxia; unable to speak. Reopened the vein bled from yesterday and abstracted fourteen ounces of blood. When seven or eight ounces of blood had been taken he began to articulate and the blueness to disappear, and when we stopped the flow respiration was full and easy. One-twentieth of a grain of antimony was ordered to be given every hour. The patient went on to recovery without any further unfavorable symptoms.

This patient was in the presence of impending death and demanded immediate relief, and what could afford that relief but the lancet?

Veratrum, digitalis, aconite, antimony could not have been equal to the emergency.

But what was the pathological condition? Was it not blood stasis, congestion in the capillaries of the lungs, closing of the air cells preventing the oxygenation of the blood?

The lungs and right heart were blocked with blood and the nerve centres were being poisoned and paralyzed with carbon, the first stage of inflammation that would soon have been followed, had the patient lived long enough, by exudation and hepatization, which timely venesection arrested. The blood-letting lessened the volume of the blood, took a load off from the lungs and the right side of the heart. Both heart and lungs had less work to do. The blood was not sent to the lungs any faster than oxygenation could take place; thus the congestion, cyanosis, and dyspnoea disappeared, and the patient was saved from impending death.

It may be said this was a case of traumatic congestion, that it differed from idiopathic disease, and that similar cases are seldom met with in practice; but all cases, however mild or severe, idiopathic or traumatic, pass through the same stages of development, fever, congestion, exudation, and hepatization. Although the extent and duration of the different stages may be various, the principles of treatment remain the same.

I will give the chief points of interest in an idiopathic case:

Dr. T. J. Mitchel, of London, and his assistant were hastily summoned at midday to see a patient said to

be dying. He was a cartman, aged twenty-six, and was quite well two days before until evening, when he was seized with difficulty of breathing, a dreadful cough, and agonizing pain in his side. His face was blue, the extremities were cold, and he was pulseless at the wrist. His feet and hands were at once put into hot water, and the doctor proceeded to bleed him. "What," said the assistant, "bleed a man pulseless and dying?" "Yes," said the doctor, "wait and see the effect."

The arm was corded and after two or three minutes a vein was prominent enough for the use of the lancet. At first the blood flowed only drop by drop, but soon increased to a continuous stream and was allowed to flow till sixteen ounces were taken, with relief from the pain and all the prominent symptoms. There was some return of the symptoms in the evening, when six ounces more of blood were taken from the same opening, with permanent relief, and in two weeks the patient was following his occupation.¹

The doctor's young friend declared as they walked from the house "that he had learned more of practical pathology, therapeutics, and physiology relating to the functions of the heart and lungs from this case and its treatment than he had gained in all his previous studies."

Recent research may have modified our views of pneumonia. Admit the disease to be an essential fever with local lung complications, that it is infectious and depends for its cause on a micro-organism, infectious or non-infectious, microbe or no microbe, the actual inflammatory changes are the same now that they were fifty or one hundred years ago, and amenable to the same treatment.

Since the days of blood-letting the profession would seem to have been largely at sea, experimenting with many different remedies and different plans of treatment for pneumonia as a substitute for the lancet. No plan yet devised seems to have met with the popular favor the lancet once enjoyed as a sort of starting-point for routine practice, subject of course to infinite variations to meet the exigencies of individual cases.

We will not weary your patience with any detailed account of these many plans, of the reasons for their adoption, and of the claimed results of each as superior to all others, but would simply suggest after what we have already said that we fall back with discretion, as a starting-point to be considered, to the old remedy that stood the test of critical observation for more than a thousand years—blood-letting.

Therapy of Acromegaly with Extract of the Pituitary Gland.—Marinesco (*Semaine Médicale*, November, 1895) reports three cases of acromegaly treated with glandula pituitaria. Two cases were of the "massive" type (a woman of fifty-three years and a man of fifty-four), and one case (a woman of over thirty years) of the "giant" type. Under the treatment the severe cephalic pains were diminished in the cases of "massive" type, but the remedy had no effect upon the neuralgic pains of the limbs. The general condition improved, but Marinesco was unable to produce the slightest diminution of the hypertrophied members. Increased diuresis was the most conspicuous effect of the treatment. Marinesco and Marie believe that acromegaly depends upon a functional disturbance of the pituitary gland, but reject the hypothesis of Tamburini and Massalongo, that the hypertrophy is a result of hypersecretion of the gland. In occasional cases section has shown that the gland had suffered a change and that the cells had been supplanted by elements of a different kind, which had not the power to supply the normal glandular secretion.

TREATMENT OF TUMORS OF THE MAMMARY GLAND.¹

BY WILLIAM L. RODMAN, A.M., M.D.,

PROFESSOR OF SURGERY AND CLINICAL SURGERY IN THE KENTUCKY SCHOOL OF MEDICINE, LOUISVILLE, KY.

I SHALL offer no apology for asking your attention this evening to a brief paper upon the treatment of breast tumors. Often as the subject has been written upon and discussed and great as have been the advances made, I feel assured that not only is the laity but the medical profession as well slow to appreciate the immense good following rational surgery practised for the relief of mammary neoplasms. This belief, or rather unbelief, has in fact some foundation upon which to rest, for it must be admitted that prior to the last decade results were unsatisfactory and surgery was justly looked upon as in the nature of a forlorn hope. Why was this so? The question is easily answered. It was due to false teaching as to the pathology of malignant growths. No surgeon believing in the constitutional origin of cancer—and nearly all did so believe twenty years ago—could look upon an operation as done to-day by any up-to-date surgeon as anything else than a dangerous and needless mutilation of the patient.

During my pupilage, which ended sixteen years ago, I have known many distinguished surgeons to remove breasts "to relieve pain," to "get rid of disagreeable odors," to "relieve the patient's mind," and only a few were optimistic enough to believe that an operation might prolong life. A cure was not thought of, much less expected. How different to-day! No one well informed believes in the constitutional origin of cancer or that the neoplasm is but the local expression of a general dyscrasia. That the disease is primarily local is accepted of all men. Then if local, why not curable by free and early removal? Here, as elsewhere, the pathologist has blazed the way for the operator and given him heart to sacrifice seemingly healthy tissue in order to get beyond the infected area, or the well-named "invisible zone." In no field of surgery is the aggressiveness of operators more to be admired than in dealing with malignant disease in general and that of the breast in particular, for it is here that the best work has been done.

To get some idea of the possibilities for doing good to suffering women, it is only necessary to remember that there are fourteen thousand deaths from cancer in the United States annually—two-thirds of these (9,333) are in women; in twenty-five per cent. of all cases in the female the lesion is in the breast, in about twenty-five per cent. in the uterus, and in fifty per cent. in other parts of the body combined. Cancer is unmistakably on the increase all over the civilized world, and an increased liability to this most dreadful disease is one of the penalties a nation pays for its material and intellectual advancement.

If surgery could promise nothing more than to add one or two years of comfortable existence to each of the 9,333 lives annually yielded up to breast cancer in this country, it would still be an inestimable boon. I shall show that it is able to cure absolutely from twenty-five to fifty per cent. of all operable cases, according to the time of applying for relief, and to prolong the lives of incurables, as well as to allay pain and smooth the way to the grave. The medical man who makes light of a lump in the breast of one of his patients at this modern day takes upon himself an awful responsibility. In patients under forty years of age the chances for malignancy in a given tumor of the breast are rather more than ten to one. Past forty they are thirteen to one. When it is further remembered that innocent growths may degenerate into

malignancy after years of quiescence, prompt action is still more imperative. Do not wait for retraction of the nipple which some suppose invariably to accompany cancer, for at most it occurs in but fifty-two per cent. of cases (Gross); other surgeons have not found it so often. Pain is even a more misleading symptom. All tumors in subjects past forty, however small and free from symptoms, should be promptly condemned to the knife.

The treatment of benign growths, solid and cystic, is simple enough. They should be removed along with their capsule, but it is unnecessary to ablate the entire organ. The nipple may in most instances be preserved and this should always be done when practicable, as it prevents deformity and leaves a gland more or less functionally active. It is not amiss to remember that innocent neoplasms are prone to affect the upper and inner quadrant of the gland. In all cases the surgeon should make an incision into the growth before removing the entire organ.

Keen, of Philadelphia, tells a good story of the immortal Langenbeck. While attending one of his clinics a patient was brought before the class with a supposed malignant tumor of the breast. Langenbeck had previously examined the case and felt certain of his diagnosis. He at once proceeded to remove the entire gland, in a rapid and brilliant manner. When the breast had been removed and an assistant was dressing the wound, Langenbeck, in the presence of the class, made a gash into the tumor to verify his diagnosis and a liberal discharge of pus was the result. He looked surprised, but with great composure said, "I never did that but once before in my life." An incision before removal of the breast would have saved the great clinician some humiliation and the woman her mammary gland.

Malignant Growths.—For all practical purposes we need make no distinction between carcinoma and sarcoma, as their treatment is the same. However, since sarcomas generalize by the blood and not by the lymphatics, it would seem unnecessary to clean out the axilla in all cases in the very thorough manner in which it is done—if the operation be rightly performed—in operating for cancer. I confess, however, that I make no distinction and it is my belief that other surgeons do not. One of the most beautiful and thorough operations that I ever witnessed was done by Keen for sarcoma. He went to the clavicle in search of glands and fat, leaving literally nothing in the axilla but vessels and nerves. There are three most excellent reasons why sarcomas demand the same thorough extirpation as cancers.

First, mistakes in diagnosis may be made and one had always best err on the side of doing a radical operation.

Second, sarcomas do sometimes cause involvement of the axillary glands; not often it is true, but if it ever occurs one should operate as if such a case was being dealt with.

Third, some of the most malignant growths ever encountered in the breast are sarcomata. I have seen one such growth in a pregnant woman destroy life within a twelvemonth. Of course the condition of pregnancy hastened its progress.

Before giving the technique of the complete or radical operation, as it is usually called—and I shall describe none other, it being the only one worthy of mention—I must insist upon the importance of educating women to believe that as soon as a lump is discovered in the breast safety depends upon getting the best surgeon to be had and getting him as soon as possible. It is all important to remove malignant tumors before involvement of the axillary and other glands has occurred, as the chances of a permanent cure are at least four times greater before than after infec-

¹ Read before the Louisville Surgical Society.

tion of these glands. It is not to be inferred that enlargement of the axillary lymph glands is of such bad prognostic import as to make such cases inoperable. Far from it, as a rightly done operation will cure ten per cent. of such cases permanently. When patients apply before such infection, at least forty per cent. may be saved, with a probable fifty or sixty per cent. Another point of importance: Patients will sometimes insist upon having only the tumor removed and that part of the breast and nipple shall be spared. This is natural, but it is a sentiment which should not be yielded to by the surgeon. The last case I operated upon was of this kind. I insisted upon being left unfettered, free to do what my judgment dictated, and declined to operate unless such was the case. As I had suspected, the tumor proved to be malignant and a very thorough operation was done, the axilla being invaded and cleared of glands and fat (of which there was a quantity) from base to apex. I have never done a more radical operation, and, notwithstanding the fact that the axilla was so radically attacked and a part of the pectoral muscle excised, the usefulness of the arm has not been in the least impaired. The crucial test, dressing of the back hair, can be as well done now, three months after operation, as ever.

Operation.—I shall now describe the radical operation as practised by a number of leading surgeons of this and other countries. A general bath should be given the patient the day before operation. The operative field should be most thoroughly disinfected, the armpit having especial attention; all hair should be removed. This being done, antiseptic gauze should protect the parts until the anæsthetic is given. A second thorough disinfection of the parts is then secured before the operation is begun. An elliptical incision—usually from the sternum to near the axillary margin—is made; but it may be from above downward (as in my last case), according to the location and size of the tumor. The amount of skin sacrificed should depend entirely upon whether it be seemingly healthy or not. As a rule too little skin is removed, and on this account regional recurrences are not infrequently seen. The incision should rapidly extend down to the pectoralis major muscle. The fascia covering it must go and every vestige of the mammary gland along with it. It is unnecessary to lose time in applying forceps until the breast has been lifted out of the way but not detached from the axillary end of the wound. Good assistants will control hemorrhage for the time being by pressure. (Most of the vessels enter from the axillary side of the wound and hence will not be cut in the first stage.) An incision is now made along the lower border of the great pectoral muscle well up into the axilla. After cutting through skin and superficial fascia, it is well to discard sharp instruments for the blunt dissector of Allis, which in this operation is simply indispensable to one familiar with its use. The axillary vein, on account of its size and color, is soon seen, and from this time on is the key to the situation. With the blunt dissector and finger nail all lymphatic glands and the fat in which they are embedded must be searched for from base to apex. The space between the two pectoral muscles usually contains some large glands and must not be overlooked. After this the space of Mohrenheim, between the tendon of the lesser pectoral muscle and clavicle, must be carefully examined for glands and fat. One can easily carry the finger into the subclavian triangle of the neck. When the axilla has been thus dealt with, vessels and nerves will stand out almost as prominently as in a dead-room dissection. One will be surprised at the small amount of hemorrhage where there are so many vessels, if one is careful to use only blunt instruments. The only danger is the tearing of some large

vein, which with reasonable care will not happen. It is important that the breast, axillary glands, and fat be removed *en masse*. In this way no lymphatic channels are cut across, liberating juices and cells to infect healthy tissue.

The removal of the pectoral fascia has been shown by Heidenhain to be all important. The infiltrations of the disease will usually be limited by this fascia, but it is now and then necessary to excise a portion, perhaps most, of the muscle. It has not been shown, however, that Halsted's plan of invariably removing the great pectoral muscle in its entirety is necessary or advisable. Willy Meyer goes farther than Halsted and removes the lesser pectoral muscle at the same time. Halsted also removes the supraclavicular glands in all cases. I do not think surgeons will follow either Halsted or Meyer in their more radical procedures, as most of these operations are in elderly women, for which reason shock should not be increased and prolonged without compensatory advantages. As yet such advantages have certainly not been proven.

The wound should now be thoroughly dried. This is most important, if the ideal method of dispensing with drainage is to be followed. A large dead space is left, and unless accurate approximation of the sides and edges of the wound is secured suppuration will ensue. This, in my judgment, can be done and primary union secured, as a very general rule. Some surgeons, as Keen, prefer to drain with the tube for twenty-four or thirty-six hours; others do not drain at all. The latter method is the ideal one and the one most generally followed. I never use a tube myself, but cut an elliptical hole at the most dependent part of the axilla, which I find drains admirably well if the fat along the edges of the opening is freely removed. I formerly introduced iodoform gauze as a drain, but have discarded it. The hole is all that is necessary and is free from objection. I have seen no one else follow this plan nor have I known of its being recommended. The wound is now carefully brought together by interrupted silkworm-gut sutures, care being taken to avoid tension. Where the skin is scant one can by undermining it slide the flaps so as to gain space. (Shrady and others follow this plan.) If too much skin has been sacrificed for approximation, one must either treat the case as an open wound or immediately skin graft by the method of Thiersch and in this way avoid a tedious convalescence. In applying the dressing it is necessary to make firm pressure under the axilla so as to obliterate the dead space left behind. If this be not done fluids will accumulate and suppuration ensue. There is no more important step than the application of the dressing. I never, as in many other operations, trust this to an assistant, no matter how fatigued I may be. The arm should be confined to the side in the Velpeux position for forty-eight hours, afterward it may be freed. Some patients will complain of this position, and when they do I free the forearm, keeping the arm firmly bandaged at the side. This, as a rule, gives prompt relief. I change the dressing at the end of twenty-four hours, no other dressing being done until the sixth day, when I remove part or all of the stitches. My cases very generally run an afebrile course and the patients sit up in forty-eight hours. A dose of morphine is seldom necessary.

Mortality.—The English, with whom the complete operation originated but who, strange to say, do fewer such operations now than are done by surgeons in this country, Germany, and France, would have us believe that the mortality following it is much greater than after simple excision of the gland. This would seem *a priori* to be the case, for opening such an important space as the axilla, filled as it is with many large vessels and nerves, is calculated to increase shock, to

cause a greater loss of blood, and if not aseptically done is likely to be followed by sepsis variously manifested. But the statistics of American and German surgeons doing the complete operation are much better than the showing made by our British brothers, not only as to ultimate cure but as to mortality. Butlin, Treeves, and Williams, of the English, all recent writers, place the mortality as high as ten per cent., which in the light of less than one per cent. mortality of six American surgeons whose results have been published within the last year seems extraordinarily high and cannot be understood unless old statistics are included: for certainly the principles of a sepsis—and that is all there is to it—are as well understood and carried out in England as anywhere. In my limited experience I can well remember when a breast amputation was a serious operation, and during my service in a Philadelphia Hospital in 1879 and 1880 there were deaths from erysipelas, pyemia, and secondary hemorrhage, the result of sepsis. Billroth at one time admitted a death rate in his own practice of twenty-three per cent. Asepsis has done as much for this operation as it has for laparotomy, and it is as unfair to call out old statistics for the one as for the other. I once heard the greatest surgeon this country has ever produced (S. D. Gross) say that ovariectomy was an unjustifiable operation on account of its dangers. *Tempora mutantur et nos mutamur in illis.* With the careful training students get to day, both in theoretical and clinical work, the tyro who flashes his maiden knife may look for better results than a master of bygone days. The results of Keen, Bull, Dennis, Weir, Halsted, and Powers, six Americans who within the year have published their statistics, show a mortality of less than one per cent. (six hundred and fifty-six operations and six deaths). This number of cases reported by entirely reliable men is sufficient to settle forever the fact that the death rate cannot be excessive. I should say that it will be two or three per cent. with the average operator. In my own practice I have never lost a case nor had cause to feel the least anxiety about a patient.

Ultimate Results.—We now come to the vital question, are women permanently cured by operation and, if so, how often? Having served under S. W. Gross in Jefferson Hospital, in 1879, when he was about the only one in this country doing the radical operation, and knowing of his excellent results by seeing some of his patients years after operation, it is but natural that I, in the beginning of my professional life, became a believer in the curability of breast cancer. To doubt was, as Virchow recently said, "to resist the brute force of facts." On other occasions in this society I have taken advanced grounds on this subject and perhaps made myself liable to the charge of optimism. I am prepared to go farther to-night than ever before, and shall give statistics from unquestioned sources to justify my position. From the twelve per cent. of cures claimed by Gross and Banks in 1880 we have gotten to the twenty-five or fifty per cent. of 1895. Until recently Bull, of New York, with 26.6 per cent. of recoveries, held the record. Dennis, of New York, the late president of the American Surgical Association, in his address before that body in May last, gave the result of his life work in malignant disease. He had records of thirty-eight breast amputations for carcinoma, seventeen of which had passed the three-year limit and were justly called permanent cures. This is forty-five per cent. He also reported 66.3 per cent. of cures in sarcomas of the breast (six cases, four recoveries). This is too small a number to generalize from. It will, however, be admitted that the prognosis in sarcoma should, as a rule, be somewhat better than in cancer.

For complete details W. T. Bull's series of one hun-

dred and eighteen cases is still the most satisfactory yet published, as he leaves nothing to be conjectured. Forty per cent. of his cured cases had axillary involvement, as shown by microscopical examination. In cases where there was no such involvement he secured fifty-four per cent. of cures.

Halsted's series of seventy-six cases was apparently a good showing, but sufficient time had not elapsed since operation in nearly all of his cases. Keen, unfortunately, has not kept a record of all of his two hundred cases, but thinks we should get from twenty-five to fifty per cent. of cures.

I will close with the following propositions:

First, all mammary growths should be removed at once, for innocent tumors carried for a long time become a menace.

Second, the complete operation should always be done in cases of malignant disease.

Third, in nearly every case it is simply impossible to detect enlarged glands until the axilla is opened. Keen says that he cannot do so once in ten times.

Fourth, the mortality should be with average operators about three per cent.

Fifth, a radical operation should promise from twenty-five to fifty per cent. of permanent cures, according to the time when patients apply.

Sixth, when in doubt operate; never wait for symptoms.

NOTE ON THE USE OF PERMANGANATE OF POTASSIUM IN THE TREATMENT OF DISEASES OF THE SKIN.¹

BY L. DUNCAN BULKLEY, A.M., M.D.,

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL; CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

REMEDIES which are able to give efficient relief to pruritic conditions of the skin are so relatively few that each addition to the number is not without value, although the range of its applicability may not be so great as might be desired. In the following very brief communication I wish to call attention to a remedy which has served me excellently in a considerable number of cases of eczema, and also somewhat in other pruritic eruptions, during the past two years, and which I am prescribing with increasing confidence.

It is quite possible that its use is known to many, but as I learned it accidentally from a patient and have not seen it mentioned in text-books or journal articles, I feel that it cannot be very widely employed.

Briefly, it is simply a solution of permanganate of potassium in water, in a strength of from one to two per cent., or possibly stronger in certain cases. This is brushed or mopped over the surface and allowed to dry, which it does very quickly. The well-known brilliantly pink or magenta-colored fluid turns very soon to a medium dark brown, staining the skin for some little time, and is finally thrown off by exfoliation of the tissues which it has oxidized.

Thus far I have used it mostly on subacute eczema, exhibiting patches of erythematous or papulo-squamous surface. I have not commonly employed it on moist or weeping surfaces, but recently a patient applied it to such on the thigh with most beneficial effects. It may sting or smart a little if the surface be at all abraded, but this is never complained of, and patients speak only of the immediate relief from the itching in the part which it affords.

I have frequently had a little calamine and zinc lotion sopped on after it was dry, mainly to guard against any excessive action of the permanganate.

¹ Read before the New York State Medical Society, January 23, 1896.

When the surface has tended to dry up too much, I have had a little mild or negative ointment applied after the permanganate was quite dry.

The application of the solution of permanganate needs to be repeated, perhaps twice daily, and some patients have used it oftener with advantage.

As it is an oxidizing agent, it often serves very well in reducing thickening of the skin, and I have seen patches which had resisted other treatment melt away under its use.

Although I have mentioned applying another lotion or an ointment over the dried application of the permanganate, there is no question whatever as to the effect of the remedy under consideration. In some cases it has been employed alone, and in other instances the patient has voluntarily omitted the additional local medication, finding that the permanganate alone sufficed to give relief; not infrequently where other remedies had been employed ineffectively the addition of the latter secured the desired result.

It is understood, of course, that in thus recommending a particular local application I do not advise it to the exclusion of other and proper dietary and internal medical treatment, nor do I wish to exaggerate its special value to the deprecation of other valuable topical treatment. I only wish to call attention to a local measure which I believe is not well known, and which has helped me much in managing some rather rebellious cases.

4 EAST THIRTY-SEVENTH STREET, NEW YORK.

Progress of Medical Science.

A New Method of Performing Abdominal Hysterectomy.—At a late meeting of the British Gynaecological Society, as reported in the *British Medical Journal*, Mr. Bowreman Jessett read a paper on this subject. He pointed out that the methods of performing the operation might be divided into three classes: (1) Extraperitoneal method of dealing with the stump by the use of Koeberlé's clamp; (2) the subperitoneal method of dealing with the stump after removal of the tumor; (3) total extirpation. The objections to the extraperitoneal and subperitoneal methods were discussed. By total extirpation of the whole organ all these objections were overcome, and the author submitted certain operative details which he had carried into practice with the most satisfactory results. Hitherto, operators after removal of the entire uterus with its tumor had laced or stitched the two peritoneal surfaces of the flaps together across the pelvis, thereby restoring the floor of the abdominal cavity. Difficulty hitherto had been experienced in opening up the roof of the vagina, some accomplishing this *per vaginam*, others by having an assistant's finger passed into the vagina. To overcome this difficulty, Mr. Jessett had had a bivalved speculum made, two inches long, which an assistant passed into the vagina when the tumor was delivered through the abdominal wound; by having this instrument pushed well home the roof of the vagina was put upon the stretch, and it was easy after the anterior and posterior flaps were reflected from the tumor to cut down upon the ends of the blades before and behind and then to ligature the uterine arteries on each side; by dividing the tissues between these ligatures and the cervix the uterus and tumor were lifted out. By lacing the flaps across there was a large raw surface left which would, or might, be a source of septic trouble afterward. To overcome this he proposed that long loops of silk, some four to six in number, should be passed through these flaps at their edge, so that the knot was made to come out through the speculum in the vagina by catch-

ing the loop in a specially made instrument. When all these loops were passed they were drawn taut, and the peritoneal flaps were in this way everted and doubled upon themselves into the vaginal roof. The vagina was then packed with strips of iodoform gauze, the speculum withdrawn, and the abdominal wound closed. All the patients on whom Mr. Jessett had performed this operation had convalesced easily and well; in fact, just as after an ordinary ovariectomy or vaginal hysterectomy. He read short notes of five cases in which he had operated successfully by this plan. The chief points in the operation were: (1) The use of the long speculum passed up the vagina, by means of which the uterus is somewhat lifted up and the roof of the vagina put on the stretch, which enables the operator to cut with precision into the vagina from above. (2) The treatment of the peritoneal flaps; by everting and drawing these down through the vagina, the two peritoneal surfaces are brought into accurate apposition, and by being doubled on themselves raw surface is apposed to raw surface, and also free drainage is established at the lowest point of the abdominal cavity, through the vagina if required. (3) The flaps being drawn down in this fashion form a plug to the roof of the vagina, and the floor of the pelvic cavity is much firmer than if the peritoneum is simply laced across; moreover, by the latter method a large raw area is left which is much more likely to cause suppuration. (4) By removing the whole uterus in this manner there is very little hemorrhage, and no need for the use of elastic ligatures or other means for constricting the neck of the tumor. (5) The patients suffer no more pain or inconvenience after the operation than after an ordinary ovariectomy. There is no dragging on the stump, and the abdominal wound is not dragged in afterward as in those cases which have been treated by the *serre-neud*.

The Infectious Nature of Lacunar Tonsillitis.—Under the title of tonsillitis or angina lacunaris, or, as it was formerly called, follicularis, Dr. Fraenkel understands an inflammatory affection of the tonsil which is distinguished by its phenomena and course as a disease *sui generis*. It begins in the majority of cases with a rigor and rapid rise of temperature. Simultaneously or after a short delay the patient experiences a sense of uneasiness in the throat. Swallowing, and particularly swallowing saliva, causes him some pain, though this is usually insignificant, and even when he is not swallowing he feels that the throat is not normal, or rather that some slightly painful change has occurred in it. In some cases these subjective phenomena precede the rigor by a few hours (*British Medical Journal*). If the throat is examined at the beginning of the illness the palatine tonsils are seen to be red and swollen. A few hours later whitish elevated spots make their appearance, and these prove on closer inspection to be drops of secretion issuing from the orifices of the lacunæ. These may be seized and pulled away, and if this is done they usually become drawn out into threads, which retain an attachment to what is left behind in the lacunæ. Fresh secretion is formed and expels what is already present, and in this manner drops of secretion reform at the lacunar orifices. They finally gravitate downward, and may coalesce with similar drops from neighboring lacunæ. In this way a larger or smaller extent of the surface of the tonsil may be covered with the whitish secretion. The latter is of a dense-fluid consistency and adheres fairly firmly to the underlying parts. It is, however, not a pseudomembrane, for it may be removed without any injury to the surface on which it lies, and proves on microscopic examination to contain no fibrin. It consists in the main of large numbers of cells (chiefly leuco-

cytes, together with epithelial cells) which exhibit granulation and the other usual indications of impaired nutrition. Besides the cells, micro-organisms (chiefly cocci) are present in crowds; but, as said before, there is no fibrin. With the further progress of the disease the redness and swelling of the tonsils increase, but these phenomena as well as the pain in the throat usually keep within moderate bounds; while, on the other hand, the fever advances with rapidity, a temperature of 103° F. and more being reached as early as the first evening of illness. Next morning the fever remits, but again rises in the evening, until during the night of crisis the temperature sinks to normal, with the occurrence of perspiration and urinary sediment. In some cases the fever ceases even within twenty-four hours of onset, in others it lasts three or four days. In all cases, however, it gives us, by the suddenness of its onset and by its termination in crisis, the impression of an infective fever, an impression which is strengthened by the disproportion which exists between the local phenomena and the height of the fever, while it is further supported by the fact that in a fraction of all cases a swelling of the spleen is to be detected. Lacunar tonsillitis is an infectious disease; for the infection to become active an injury to the organism must be added. The infective agents may reach the parenchyma of the tonsils by way of the lymph stream. The author believes that on this hypothesis the clinical and pathological phenomena of the disease under discussion are brought into harmony. It is true that many points still demand further investigation, which will be the more readily accepted the more we learn to think etiologically, or, what in these days is the same thing, bacteriologically.

The Buried Tendon Suture.—Dr. H. O. Marcy, of Boston, first suggested the use of buried animal suture. His first contribution upon the buried catgut suture was published in 1870. Ten years later (1880) he substituted tendon for catgut, claiming it in many ways superior. Catgut is defective in that it cannot be rendered absolutely aseptic. When dry the gut is strong, but when wet it is flat, elastic, and slippery. Sterilization tends to render it less strong, on account of damage to the intercellular cement substance by previous bacterial infection. The violin string (catgut) is not unlike a very thin piece of tissue silk which has been cut diagonally and then twisted. Tendon has connective-tissue cells disposed parallel to each other and is the strongest structure of the animal economy. Tendons taken from a freshly killed animal are quickly sun dried and kept dry till final preparation. Then they are soaked in 1 to 1,000 bichloride-of-mercury solution until supple, then carefully cleaned, assorted, and dried between sterilized towels. They are then chromicized until of a dark golden-yellow and then preserved in sterilized linseed oil, to which one-tenth part of crystals of carbolic acid has been added. Thus prepared they improve with age. When needed for use they are soaked in a 1 to 1,000 bichloride-of-mercury solution until supple. Prepared in the many ways suggested for sterilization of catgut serves only to injure the inherent structure of tendon and should not be recommended. Tendon taken from the tail of the smaller varieties of the kangaroo furnishes us with best suture material yet found. Dr. Marcy believes that all aseptic wounds, including even the larger amputations, should be closed in layers by buried tendon suture instead of drainage, the edges of the skin being coapted by means of parallel continuous buried suture and the wound sealed by iodoform collodion strengthened with a few fibres of cotton. The advantages of the buried tendon suture are briefly as follows: Being aseptic, and buried in aseptic

wounds it remains aseptic, and the repair is primary without inflammation, pain, or suppuration. The iodoform collodion seal renders subsequent infection impossible. No sutures are to be removed and no other dressing is required. The tendon is absorbed so slowly that it may be traced in the tissues months after inflammation, and ultimately it is replaced by a band of vitalized connective tissue which serves as a permanent reinforcement of the united structures.

Humero-Ulnar and Metacarpo-Radio-Ulnar Osteoplastic Amputations.—Samfirescon, following the ideas of Gritti and Sabanajeff, gives two new amputations designated by the above names, one at the elbow and one at the wrist. They offer as a plea for recognition the fact that they will give stumps of a better appearance and also more useful than can be procured by any methods now employed. In the humero-ulnar amputation both anterior and posterior flaps are used. The method of procedure is as follows: The joint is opened anteriorly. The posterior attachments of the ulna must not be severed. The ulna is split in the coronal plane from above downward for a distance equalling the diameter of the humeral shaft. The posterior portion of the olecranon is separated from the ulna by the saw and the forearm removed. Then the humerus is sawed across about an inch above the condyles. The bone segment from the olecranon remaining attached to the triceps tendon and embedded in the long posterior flap is sutured to the humerus and the wound closed. At the wrist the first metacarpal bone is selected for the bone segment. The posterior half is used but it is split throughout its whole length. A single skin flap taken from the posterior and external surfaces of the thumb is used in this case. The metacarpal is sutured in position after section of the articular surfaces of the radius and ulna.—*Revue de Chirurgie*, 1895, No. 10.

Congenital Syphilis and Tuberculosis.—Dr. Hochsinger concludes that syphilis and tuberculosis can appear as a mixed infection at the earliest possible age, and that this infection may be congenital. This conclusion is based, says the *Journal of the American Medical Association*, on the clinical and anatomic investigation of three cases. The first child born of a syphilitic father and a tuberculous mother died on the thirty-first day. During life an undoubted syphilitic cutaneous eruption existed, and a simultaneous pneumonia with enlargement of the spleen and the liver led to the diagnosis of syphilis. The post-mortem examination showed an extensively distributed tuberculosis of the internal organs with large and caseous nodules that contained the tubercle bacilli. The second case concerned a child that died on the thirty-eighth day. The history, the syphilitic eruption, and a pneumonia seemed to warrant the diagnosis of syphilis. The lung was the only tuberculous organ in this case. The third case presented pronounced syphilitic lesions and death from pneumonia occurred during the sixteenth week. The section showed a chronic tuberculous broncho-pneumonia, tuberculosis of the spleen and lymph glands, and interstitial syphilitic hepatitis without tuberculosis of the liver. Hochsinger regards such cases as not uncommon and lays stress upon the necessity of examining the contents of the nodules for bacilli, in order to determine whether syphilis or tuberculosis is present. The question whether the tuberculosis was congenital or acquired cannot be determined in Cases II. and III. Of the first case it may be said with certainty, however, that the syphilis was the result of a spermatoc or paternal infection and that the tuberculosis was due to a placental infection, because the caseous masses with tubercle bacilli in the liver speak in favor of infection through the umbilical vein.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 29, 1896.

TO ABOLISH THE PRESENT CORONER SYSTEM.

THE absurdity of the present coroner system, so long discussed by the medical and legal professions, has at last presented itself in a tangible shape for necessary reform such as is contemplated in the well-considered provisions of a bill now before the legislature of this State. In a previous notice we gave the essential features of this proposed law and we now take the opportunity of advocating its speedy passage and of endorsing the reasonableness of the radical changes contemplated by it. As the result of a joint conference with the State Bar Association, the Medical Society of the State of New York, and various judges of the Supreme Court, the measure was framed by Mr. Tracy Becker, Prof. R. A. Witthaus, Drs. Lewis Balch, W. G. Macdonald, A. Walter Smith, M. J. Lewi, and others. Every possible effort has been made to remove the position of medical examiner, for which it provides, from the field of political influence, and to that end the appointing power is vested in the appellate division of the Supreme Court. The bill also provides that the medical examiner shall perform his duties as an independent expert who is not in the employment or under the direction of one side or the other in any case. It is, however, by no means intended that the medical officers shall exercise judicial functions, as is now done by the coroners, but that under all usual conditions their duties shall be limited to the determination of the cause of death. The provision for clothing the medical examiner with strictly judicial functions, to be exercised in exceptional and emergent cases, needs no argument in proof of its real necessity or practical utility. Under such circumstances the medical examiner will be in a position in which he can secure evidence not obtainable otherwise, and which might be of crucial importance to all parties concerned. In all ordinary cases the purely civil and judicial functions of the proposed law will be relegated to the district attorneys of the different counties and to the courts.

The appointment of a competent pathologist and of an expert chemist as advisors to examiners leaves nothing to be desired in making use of all the necessary means to the end of securing absolutely impartial and thoroughly trustworthy testimony in the most difficult and obscure cases. Other provisions in this bill,

regarding cases of alleged insanity and drunkenness in criminal actions in which the medical examiners are called upon for expert testimony, are in a measure the foreshadowing of the practical application of the principles upon which may be founded the creation of expert commissions in the still more comprehensive sense, as already advocated in these columns.

The conditions on which the proposed reforms are advocated are of vital importance and of far-reaching significance. Instead of a coroner, who may be the merest political accident and with none of the essential qualifications for responsible work, we are to have a thoroughly competent medical man, an expert in his line, capable of everything practical in scientific and judicial inquiry, and who obtains his position from real merit as judged by competent and impartial authority. This contrast with the present system is too obvious to require comment. The time has now come when every medical man can exert his influence for good upon his representative and do his best, in an individual as well as in a public capacity, to secure the passage of this timely, comprehensive, and practical measure. The coroner and his jury have outlived their usefulness, and should no longer hinder by their legal privileges the requirements of advanced science or the demands of higher equity. The only opponents to the bill are those who can possibly profit by the coroner system as it now is, politicians who are always ready to accept any office for pay, and whether competent or not are ever ready to be tempted by large salaries to discharge nominally the most weighty responsibilities. We have now, however, come to a time when a change is likely to be made, and that the good men and true throughout the State who are in favor of it may be successful is our earnest wish and confident hope.

A RADICAL CURE FOR SICK HEADACHE.

WE have received a pamphlet entitled "Migraine, its Causes and Radical Cure," written by Dr. J. H. Kellogg, of Battle Creek, Mich., a member of a great many learned societies. The writer believes that "every case of migraine is capable of being radically cured." He further believes and states that, from his standpoint, "migraine is no longer a complex or mysterious nervous malady," but is simply a state of systemic poisoning, the origin of which is decomposition of food produced in a dilated and prolapsed stomach.

Migraine, or sick headache, is one of the commonest maladies of the age, and the news that its nature is not mysterious and that its radical cure is possible will certainly awaken some interest. We have read, therefore, Dr. Kellogg's pamphlet, in order to see the grounds upon which he makes such strong and optimistic statements. He gives a history of what he seems to think is the pathology of migraine, though his literary researches do not seem to have touched any scientific contributions later than two decades ago. The view that migraine is a disease of the sympathetic, as quoted by Dr. Kellogg, is certainly a very thoroughly exploded idea, if recent neurological works can be depended upon. However, leaving this matter

aside, it seems that Dr. Kellogg has hit upon the master-key of the trouble in the researches of Glenard, Bouchard, and their followers. Some years ago Dr. Glenard tried to show that a great many serious nervous symptoms come from dilatation and more or less prolapse of the colon and stomach. Even before Glenard's time a German writer had noticed the fact that some people had hyperæsthetic spots when pressure was made deep into the abdominal cavity. Dr. Kellogg has described these spots again, and placed them and the prolapsed viscera in relationship with migrainous attacks. He thinks that the primary nervous seat of migraine is the abdominal ganglia of the sympathetic system, with perhaps some involvement also of the cervical sympathetic. A chronic toxæmia from dyspepsias due to dilatation of the gastro-intestinal tract, combined with more or less displacement of the digestive organs, is said to constitute the cause of migraine. The objections to such a view as this are simply and easily stated, but are also complete and overwhelming.

Migraine is, according to clinical writers on this subject, a disease of childhood and early youth. The large majority of attacks begin before the age of twenty-one. Now, dilated stomach and enteroptosis do not occur until a much later period of life. This fact alone, we think, would be sufficient to show the weakness of Dr. Kellogg's theory. Common experience, however, further shows and has long taught that diet has comparatively little effect upon attacks of migraine. Dr. Haig, to be sure, has written many articles in which he tries to show that the disease has some relation to the production of uric acid. But we do not think that his view is accepted as expressing more than a part of the pathology of the disorder.

There is no doubt that during middle and later periods of life headaches of a toxic character develop, and that migrainous attacks are increased and accentuated by disorders of digestion. Therefore, although Dr. Kellogg's pathology is totally wrong and his familiarity with the disease of which he writes conspicuously slight, yet we wish to do him justice, and the suggestions that he makes for the treatment of persons with periodical headaches may not be without value. The doctor lays down four principles to be followed in the care of such cases: First, an antiseptic dietary; second, washing out of the stomach and the use of intestinal antiseptics; third, the employment of measures by which the general health and the digestion are improved; and, fourth, mechanical measures for the relief of the prolapsed stomach, bowels, or other viscera. So far as the antiseptic dietary goes, that laid down by Dujardin-Beaumetz is the one accepted by Dr. Kellogg. We should judge, however, that the writer on migraine is a vegetarian, because we find no mention of meats, which form, unquestionably, the most important part of an antiseptic diet. A good deal is said about peculiar forms of kumyss and unfermented breads as well as about malted gluten, in which the pure wheat gluten—a nitrogenous substance, by the way—has been subjected to the action of diastase, which has no action at all upon gluten! A patient suffering from migraine, says the writer, should

either abstain wholly from starchy foods or should, if he continues them, avoid entirely the use of acids and acid fruits, including such things as rhubarb. Tea and coffee should also be excluded in connection with the starchy dietary. The non-starchy dietary recommended is composed of kumyss, eggs, nuts, fruits, and green vegetables. The patient's stomach is washed out regularly, usually two or three times a week, and the best time is at night, five or six hours after the last meal. Recommendations are further made of the use of electricity, abdominal massage, and abdominal supporters of various kinds.

We have referred to Dr. Kellogg's contribution on the subject of "Migraine" at some length, because the claims that he makes are large and are stated with much detail, and, apparently, with full confidence in their value. It seems to us likely that many patients would get a great deal of useless treatment and that many physicians would be led into wrong lines of work if they accepted Dr. Kellogg's assertions.

A LAYMAN ON THE ANTITOXIN TREATMENT OF DIPHTHERIA.

MR. DEMETRIUS C. BOULGER is his name, and from his name we should guess that his extraction was Armenian, while from his temper we should judge that, like other Armenians, he has a keen sense for atrocities. Mr. Boulger voices his plaint in the *Contemporary Review* of recent date and tells a story of infinite suffering, due, as he thinks, to the present "fanatical" and "hysterical" craze for the use of antitoxin in diphtheria. Mr. Boulger admits that he is not a doctor, but he has been crammed for the purposes of his article by a doctor who has seen 15,000 cases of diphtheria and does not believe in antitoxin, but who has not the courage to come out and say so.

Mr. Boulger's tale is simple, and is essentially this:

He was suddenly attacked while in London with a severe form of faucial and laryngeal diphtheria. He was taken to a fever hospital, and there, without being questioned, he was injected with antitoxin of double strength. He was given also brandy, iron, and chlorine gargles. He received a second injection of the antitoxin and, perhaps, a third. The course of his fever, however, was not interrupted. Nevertheless, he got well, despite the malignant character of the case—and treatment—and within a month went home, against the advice of his physician. Thereupon he began to suffer from weakness in the arms, legs, and throat, which weakness, he naively adds, was turned into a paralysis by the bad treatment of his physician. In a short time he was suffering from a post-diphtheritic multiple neuritis. This disease ran its regular course, and he eventually, in three or four months, became completely well. Mr. Boulger seems to think that his experience is something extraordinary and, in particular, that this paralysis is quite out of the range of the usual experience. His conclusion is, first, that the course of his disease was not modified at all by the antitoxin, and, second, that the multiple neuritis which followed the fever was due to the use of the serum

injections. His first conclusion may be right, but as to the last it is as ludicrous a specimen of the *non sequitur* as was ever put forward in the pages of a review which aims to present contemporary thought.

The clinical history of diphtheria shows that such cases of paralysis as that of Mr. Boulger are by no means infrequent, and were recorded and recognized long before the use of antitoxin was introduced. In many epidemics ten per cent. of the cases of diphtheria have been followed by paralysis; Cadet de Gassicourt observed one hundred and twenty-eight palsies in nine hundred and thirty-seven cases, and it has been estimated that, if all diphtheritic patients lived, one out of every four would have diphtheritic paralysis. On the other hand, experiments made with the antitoxin serum have failed to show that this substance leads to any form of neuritis. Mr. Boulger's post-diphtheritic line of thought is most distressing, but perhaps the subtle influence of diphtheria with antitoxin does sometimes disturb the reasoning powers of even well-trained individuals. We would not argue against Mr. Boulger on this thesis.

However, Mr. Boulger's article does not end here. He passes from his own case to those of others. He cites his hospital experience and his hospital observations, and argues about the invalidity of statistics. The point which he makes as regards the latter has been well taken several times before, but our critic gives us nothing to offset, in any wise, the steadily increasing weight of evidence from all parts of the world that the use of antitoxin has a specific effect upon diphtheria. We will admit that even now there is a possibility of there being some other interpretation put upon the facts that are accumulating, but to the unbiassed mind it seems impossible to interpret them at present in any other way than by supposing that there is an immunizing and protecting property in the Behring serum.

We have given some prominence to Mr. Boulger's article for the reason that it appeared in a conspicuous journal and is likely on that account to be received as having authority. We predict, in fact, that before long there will be an Anti-antitoxin Society in England.

SUSCEPTIBILITY OF CHILDREN TO TYPHOID FEVER.

IN the January number of the *Archives of Pediatrics* the above subject is discussed editorially and in an article by Dr. W. P. Northrup. It has long been known that typhoid fever is extremely rare in children under the age of three years. The records of four of the largest children's hospitals of this country show that not a single patient under that age had been attacked with typhoid fever for many years. Not a single case had ever occurred in the New York Foundling Asylum in twenty years. Dr. Northrup, however, now reports four cases of typhoid fever in children of thirteen, sixteen, and twenty-two months of age. These cases occurred in a very severe epidemic which prevailed at Stamford, Conn., last year, and during the course of which four hundred and six persons were infected. Dr. Northrup reports another

case occurring in a child of two years. In this instance the mother had lain in bed for three weeks with undoubted typhoid and the child had slept with her. Three other cases in children under the age of three are reported. From these three cases it is inferred that typhoid, when it does attack children, appears in much the same form as in adults, and the characteristic eruption is one of the most valuable points in diagnosis. There can be no doubt, despite the report of these cases, that children under three, and especially those under two, years of age are almost immune to typhoid. We say "immune" for the reason that children under two, although they do not take this disease, are still, many of them, fed upon milk, which is now recognized as one of the great sources of this disease. The condition which is most commonly mistaken for typhoid fever is, according to the editor of the *Archives of Pediatrics*, catarrhal pneumonia, a disease in which the physical signs are often obscure. "Grippe," with slowly developing pneumonia, fevers that result from gastro-intestinal disease and from pleurisy, as well as the fever of tuberculosis, have all at times been mistaken for typhoid.

THE TRAINED NURSE.

WE all cheerfully and willingly acknowledge that the modern trained nurse has been a great acquisition to society, lessening the danger and suffering from disease and promoting vastly the comfort of households in which sickness appears. These sentiments have been frequently expressed in our columns, and are, we feel sure, common to all members of the medical profession. At the same time there is a feeling that this modern angel is not an entirely perfect being—that there is at times a rift in the lute, a haze over the stars, or, to be more strictly professional, an occasional fly in the ointment and a rigor in the ordinarily warm emolliency of the poultice. This side of the question has been recently and vigorously presented by Mr. Malcolm Morris, in *The Practitioner*. Under the head of "The Monstrous Regiment of Nurses," Mr. Morris describes with great feeling the imperfections which he thinks attend the character and conduct of the English trained nurse. The imperfection which he depicts is a tendency of the trained nurse to interfere excessively in the conduct of medical and surgical cases. They hint, he says, that doctors' prescriptions and treatment might be a little amended. They make suggestions of their own as to diagnosis and prognosis. They elevate themselves in a measure to the order of the medical practitioner himself. Their smattering of knowledge of anatomy and physiology leads them to suggest to their patients diseases which never could, by any possibility, have entered the heads of the patients themselves. To a person with a stomach ache they talk "peritonitis" and "appendicitis," and to a person with eczema they talk about "lupus" and "scleroderma."

These are the charges, or some of them, which Mr. Morris makes, and he cites some very striking illustrations of the presumption and magnification of the

English trained nurse. American physicians have also seen something of this seamy side. We do not know that the particular troubles described by Mr. Morris are the predominant ones here. What most physicians do see is that the average trained nurse often develops into a trained gossip of the most lugubrious and exaggerated type. A large majority of them seem to think that, after their strictly technical work is done, the proper thing is to sit down and tell the patients about all the cases they have ever seen or nursed in their lives. As a result the convalescent listener is left with her mind full of extraordinary pathological tales that have an unpleasant, lasting, and pernicious effect upon her mental make-up. The trained nurse of to-day, also, has so exalted her office that she is very frequently unwilling to do anything but attend to purely technical work. The idea of touching a duster, or of attending to the care of the room, or of doing anything but pouring out medicine, putting on the proper applications, and taking temperatures in the most ladylike way, becomes revolting to the majority of them, so that one often sighs for the old-fashioned nurse, who would settle down and do everything for \$10 a week. There seems, indeed, to be rather a need, not only of the trained nurse, but of a modest and half-trained nurse, who will make fewer pretensions, charge less money, talk less about her profession, and attend more strictly to business.

News of the Week.

The "X" Rays.—The new rays have been discovered to exist in the flame of a Bunsen burner and of a paraffin candle, though they are much weaker. Professor Salvioni, to whose work in this line reference has been made in a previous issue, now claims to have discovered a means by which these radiations may be made to assist the eye so far as to enable it to see through all objects which the rays can penetrate, thus revealing the contents of a closed space.

Medical Law for Ohio.—Ohio has at last a law regulating the practice of medicine. The bill passed the Senate on February 19th.

The Camden County (N. J.) Medical Society celebrated on February 11th the fiftieth anniversary of its organization. The formal ceremonies included a visit and inspection of Cooper Hospital, an address of welcome by the president of the society, Dr. Alexander McAllister, an address on "The Medical Profession of Camden County," by Dr. E. L. B. Godfrey, the presentation of busts of the late Dr. Richard Maltack Cooper and of the late Dr. Othniel H. Taylor, and finally an elaborate banquet.

The Bill for the Adoption of the Metric System, introduced into the House of Representatives by Mr. Hurley, is now before the committee of coinage, weights, and measures.

Thirty-nine Verdicts of death by starvation were brought in by London coroners' juries last year.

A Medical Law to be Repealed.—The Senate committee on military affairs favorably reported the bill repealing the existing law which requires surgeons and other medical officers of military homes to be persons who have been disabled in the military service of the United States.—*Journal of the American Medical Association.*

Obituary Notes.—DR. HENRY HOUSE, of Rockland Lake, N. Y., died February 21st, of injuries received when he was struck by an engine on the West Shore Railroad near Congers. He was born in Ulster County, in 1842, and was the son of Captain Garrett O. House, who was well known as a pilot on the Hudson for many years. Dr. House was graduated from the medical school of the University of the City of New York in 1863. For a few years he was engaged in the drug business at Haverstraw, but afterward he entered upon the practice of his profession at Rockland Lake. He had been for a long time the only resident physician in that place, and, as school trustee and health officer, he was well known throughout Rockland County. He was also conspicuous in Masonic circles. He left one brother, Dr. William S. House, of Haverstraw, and two sons, Clarence and William.—DR. DAVID L. DAGGETT, aged seventy-five, died at his home in New Haven February 23d, of pneumonia, after three days' illness. He graduated at Yale in 1839 and at the Yale Medical School in 1843. Dr. Daggett had been president of the New Haven Medical Society, president of the New Haven County Medical Society, and a member of the Connecticut Medical Society since 1843.—CORONER WILLIAM O'MEAGHER, aged sixty-five years, died at 10:45 P.M., February 25th, at his residence, 427 East Eighty-fourth Street. On February 18th Dr. O'Meagher had a congestive chill, and he apprehended pneumonia from the first. On the following day he sent for his family physician, Dr. Dwyer, and for Dr. O'Hanlon. Symptoms of pneumonia had developed, and the doctors were compelled to remain with the patient continuously. On February 22d there was a marked improvement in Dr. O'Meagher's condition, but a relapse came on the Sunday following, and Dr. Janeway was consulted. February 25th Dr. O'Meagher sank rapidly. He was born in Ireland, and entered the British naval service as a surgeon, and later came to the United States. Here he served in both the army and the navy, and in the war won honors for bravery while fighting as a member of the famous Irish Brigade. After the war he came to New York to be treated for a bullet wound. He then joined the Grand Army of the Republic. He practised as a physician in this city, and was a deputy coroner under John R. Nugent. In 1894 he was nominated for coroner on the combination Republican and Reform ticket and was elected. Governor Morton has the power to fill the vacancy.—DR. JOSEPH JONES, of New Orleans, died on February 17th.—DR. WILLIAM J. PURCELL, of this city, vaccinator in the public schools, who has held a place in the bureau of contagious diseases since May, 1875, died on February 21st at his home at College Avenue and 164th Street.

The New York Red Cross Hospital.—Papers of incorporation have been granted to the New York Red Cross Hospital, founded under the auspices of the American National Red Cross Society, of which Miss Clara Barton is the honored president. It is under the immediate oversight of the New York branch of the Red Cross Association. It is the first and as yet the only hospital in the United States that performs Red Cross work, and as such receives patients of all nationalities, whether they are naturalized American citizens or not and irrespective of the time of residence in this country, especially so when sent by a consul-general of a foreign nation; likewise any member of the navy, army, or State militia when sick or disabled. The consulting staff is composed of Drs. T. Gaillard Thomas, George F. Shrady, Augustus G. Caillé, and William H. Porter; the visiting staff of Drs. A. Monae Lessèr, C. Ruston Ellison, Thomas A. McNicoll, H. Gottlieb Steger, Emil Mayer, and Adolph Zek. All medical men of the navy, army, and State militia are by virtue of their office associated physicians and have the right to treat personally all cases sent by them to the hospital.

Department of Public Health for Mississippi.—A bill has been introduced in the legislature of Mississippi providing for the creation of a department of public health under the control of the licensed medical practitioners of the State. The functions of the department are to comprise a general superintendence over the health interests of the State; the collection of vital statistics; the development of medical literature; the prescribing of rules and regulations, with a specification of duties for the conduct and reports of the committees; the investigation of the hospitals, asylums, and other like institutions in the State; the causes, means of prevention, and treatment of endemic and epidemic diseases; and the influences of localities and employments upon the public health. It is to act also as an advisory board to the State in all hygienic and medical matters, and auxiliary boards in the different counties are to be formed under the direction of the central board.

Official Indifference to the Spread of Tuberculosis in Vienna.—Professor Schrötter, of Vienna, commented very severely in a recent lecture on the refusal of the government to take any measures against the spread of tuberculosis.

Leprosy in Canada.—It is proposed to transfer to Tracadie, N. B., nine lepers now held in confinement in British Columbia. A new lazaretto costing about \$20,000 was recently erected at Tracadie. There are now nine male and sixteen female patients in the hospital. Three died during the past year. For many years Dr. A. C. Smith has been in charge of this institution. Regarding the result of his experience with leprosy patients, he says that no specific cure for leprosy has yet been discovered. His predecessor, Dr. Nicholson, and also Dr. Smith treated several of the lepers with colored water, to see if the influence of the mind over the body would cause a change, and in every instance it did so. For a time all symptoms of

the disease were in abeyance and there was a decided improvement, but this was only for a time, and it seemed as though the disease made up for lost time afterward.

Quarantining a Hospital.—The New Haven Hospital has been quarantined under a special cordon of police because of the discovery that one of the nurses is ill with small-pox.

Dr. Henry H. House, a physician of Congers, was struck by a south-bound train on the West Shore Railroad a few days ago. Physicians who were summoned from Haverstraw and Nyack found that he had sustained very severe and fatal injuries of the head. Death occurred the day following.

Mr. John Petch Hewly, a surgeon of London, but better known as "Pembridge," the author of several works on whist, died recently at the age of sixty-one years. Another authority on whist, "Cavendish," was also a medical man.

The Insane in California.—A California paper comments on the fact that that State, with fewer inhabitants than New York City, has five great insane asylums, with about forty-five hundred patients.

A Combination of Druggists.—More than four hundred retail druggists of Chicago have combined to fight the cutting of the prices of drugs and medicines by department stores, and to combat at the same time the sale of medicines by the manufacturers and wholesale dealers to these stores. They have organized a company, leased a manufactory, and will begin at once the compounding of all kinds of blood purifiers, cough mixtures, and tonics. All the drug stores in the combination will draw their supplies from the factory at prices so low that they expect to undersell the "cut" rates of the department stores.

The Prevalence of Tuberculosis.—Professor Köhler, Imperial German Health Officer, has found in the cases examined by him symptoms of tuberculosis in the body of every third person who died between the ages of fifteen and sixty.

Rejection of Recruits.—Nearly one-third (15,000 out of 50,000) of the men who wanted to enter the British army last year were rejected on account of defective eyesight, bad teeth, or flat feet.

An Antitoxin of Tuberculosis.—Dr. Aronson, of Berlin, has succeeded in infecting a goat with tuberculosis and in making other goats proof against the disease.

The Entering Wedge.—Göttingen has thirty-one woman students this winter semester. They study history, mathematics, modern languages, and natural history, and for the first time at this university a woman is studying medicine.

The Lehigh Valley (Pa.) Medical Association held its eighth winter conversational meeting at Allentown on January 30th. Papers were read as follows: "Some Aspects of Bacteriology in Their Relation to the Practice of Medicine," by Dr. George W. Best, of Lambertville, N. J. "Electro-Therapeutics for the General Practitioner," by Dr. Israel Cleaver, of Read-

ing, Pa. "Fractures of the Skull," by Dr. H. M. Keller, of Hazleton, Pa. "Disinfecting Methods," by Dr. Charles McIntire, of Easton, Pa. The next meeting will be held at Wilkesbarre in the spring. The following officers were elected for the ensuing year: *President*, Dr. G. L. Romine, Lambertville, N. J.; *Vice-Presidents*, Dr. W. H. Hartzell, Allentown; L. W. Moyer, East Mauch Chunk; J. W. Keath, Shaefferstown; Mary Greenwald, Stroudsburg; *Secretary*, Dr. Charles McIntire, Easton; *Assistant Secretary*, Dr. W. S. Stewart, Wilkesbarre; *Treasurer*, Dr. Abraham Stout, Bethlehem.

The Deadly Oyster.—In the fifteenth annual report of the New York State Board of Health, recently issued, is an account of an investigation of the typhoid-fever epidemic, attributed to infected oysters which were freshened in water contaminated by sewerage, at Port Richmond, made by Dr. E. C. Curtis. His opinion is that not only typhoid fever but cholera and diarrhoeal diseases may thus be transmitted.

The Leading Universities.—Berlin, Vienna, Madrid, Naples, Moscow, Budapesth, Munich, Athens, are the first eight European universities, in the number of students attending courses of lectures, according to "Minerva," the year book for the universities of the world. Harvard is ahead of Oxford and of Cambridge.

Acetylene Gas.—A petition was introduced into the Massachusetts legislature recently praying that the manufacture and sale of acetylene gas be prohibited on the ground that it is dangerous to life and property. It is also asked that the storing of the chemicals from which it is manufactured be forbidden.

Aluminium for Cooking-Utensils.—A scientific investigation was recently undertaken by the Imperial German Health Bureau to inquire into the suitability of the use of aluminium for cooking-utensils. It was proved that this metal is entirely free from communicating to food any poisonous salt, such as is given off by copper, tin, or lead.

Foreign Students in Paris.—Out of 4,158 law students 230 are foreigners, and out of 5,445 medical students no fewer than 879 are foreigners—Russians, Roumanians, and Turks being the most numerous. There are also 71 foreign students—10 of them women—in the faculty of science, and 160 in the faculty of letters, 61 of them women.

Saved because His Heart was Right.—A man in Indiana was shot the other day and would have been instantly killed if his heart had been in the normal position, for the ball from his assailant's revolver passed directly through his body at the place where his heart ought to be. Fortunately the man had transposition of the viscera, his heart being on the right side. The ball touched none of the great vessels and the man will probably recover.

The Growth of Proprietary Remedies in the West.—An analysis of 10,000 prescriptions made by the committee on revision of the United States Pharmacopœia of the Illinois Pharmaceutical Association

shows that in 2,613 prescriptions, or about one-fourth of the whole number, proprietary remedies were prescribed.

The Rout of Quackery in Kentucky.—Under this head, the *American Practitioner and News* gives an account of the results of the present law regulating the practice of medicine in Kentucky. It is said that the placards, signs, and showbills of quacks, which used to stare one in the face in every public place, are no longer seen, and that those who practise medicine honestly are not now handicapped by the methods of advertising employed by these pretenders. The benefits are not limited to the cities of the State, but affect the rural practitioner as well.

University of Pennsylvania.—A committee on medical and allied schools of the board of trustees of the University of Pennsylvania has under consideration a proposition providing for the gradual elevation of the requirements for entrance upon the course of study in the medical department, until in 1899 they shall be equal to those of the collegiate department. At a later date it is possible that a collegiate degree will also be made a requisite.

The Youngest Member of the French Academy of Medicine is Dr. Raphael Blanchard, aged thirty-nine years. He is regarded as an authority on the parasitic diseases of man and the lower animals, and is now engaged upon an important zoological work.

University of Vermont.—Dr. George Thomas Jackson, of New York City, has been appointed professor of dermatology in the medical department of this institution.

Regulation of Midwives.—The Philadelphia board of health has issued as instruction to all midwives, nurses, and others having the care of infants the text of a recent act of assembly for the prevention of blindness in new-born infants. This act makes it the duty of a midwife, or nurse, or other person having the care of an infant to report in writing to the health officer or a legally qualified practitioner of a city, town, or district in which the mother of a child resides any inflammation, swelling, or redness of one or both eyes of an infant at any time within two weeks after birth. Immediately upon the receipt of such report the health officer is to notify the parents of the infant of the danger to the eyes and enclose directions for proper treatment. Failure to comply with the provisions of this act is punishable by a fine not exceeding \$200 or imprisonment not exceeding thirty days or both. The nurses are instructed to wash the eyes of the new-born infant with clean, warm water, using a soft cotton cloth. If the eyes should appear red or inflamed the attention of a physician must be called, while in the mean time they should be washed out freely with a weak antiseptic solution, such as salt and water (one teaspoonful to the pint).

A Difference.—*Criticus*—"I don't believe there's much difference between genius and insanity."

Struggling Author—"Oh, yes, there is; the lunatic is at least sure of his board and clothes."—*Tit-Bits*.

The Decadence of Doyle.—A firm of large advertisers of a quack medicine have brought out a small book in which the virtues of their commodity are set forth in all the usual blatancy of such purveyors, but as a special inducement to read the announcements the book also contains a story by Dr. Conan Doyle, which is said to be interesting. This "literary production" is intended by the firm to reach the hands of the public through the chemists who sell their concoction.—*Medical Press.*

A Female Master in Surgery.—Miss Louisa Aldrich Blake, who is curator of the anatomical museum at the Royal Free Hospital, London, is the first woman to win the title of master in surgery of the University of London.

The Antitoxin Treatment of Diphtheria at the Boston City Hospital.—At the recent dinner of the Boston City Hospital Club, Dr. J. H. McCollom gave an account of the results obtained in the department of that hospital for contagious diseases, which is of more than passing interest. He said, in part: "Since the department was opened on August 31, 1895, 1,139 patients suffering from infectious diseases have been admitted. There have been 120 deaths, giving a percentage of 10. There have been 844 cases of diphtheria admitted, with 96 deaths, giving a percentage of 11. All of these cases have been treated with antitoxin, and the result is certainly remarkable. The lowest death rate in any of the foreign hospitals for infectious diseases has been thirteen per cent., which shows that the south department of the Boston City Hospital has reduced the death rate to a lower percentage than any other hospital in the world, so far as we can learn from published reports. If we compare this death rate from diphtheria of eleven per cent. since the introduction of antitoxin with that of a death rate in the hospital of forty per cent. before the introduction of antitoxin, there can be but one opinion regarding the efficacy of the remedy. The effect of antitoxin on the operative cases has been very marked. In the report of the Boston City Hospital for the year ending January 31, 1895, before antitoxin was generally used, there were 86 cases of intubation, with 74 deaths, giving a percentage of 86. In the south department from August 30, 1895, to February 1, 1896, there were 79 intubations, with 36 deaths, giving a percentage of forty-five, a diminution of nearly one-half."—*Boston Medical and Surgical Journal.*

A Specific for Headache.—In Paris a new novel entitled "A Victim of the Guillotine" is all the rage just now. It is advertised on large posters at the street corners. By a singular chance one of these posters was partially covered by the advertisement of some patent medicine, which made it read as follows: "A Victim of the Guillotine—no more headaches."

Water Supply of Philadelphia.—For a long time the water supply of Philadelphia has been notoriously bad and a direct connection between its quality and the marked prevalence of typhoid fever in the community has been frequently pointed out. It has, however, hitherto not been possible to secure action on the

part of the municipal legislature toward improvement in this direction, but the outlook is now more promising, thanks to the constant agitation of the subject by hygienists and by a number of public-spirited men and women. The city councils have recently approved an ordinance appropriating \$250,000 for the erection of one or more experimental filter plants and it is earnestly to be hoped that there will soon be provided a water supply that is unobjectionable from every modern point of view.

The Whole Scientific World has been set into agitation by the announcement of the discovery of the new form of light by Professor Roentgen of Würzburg and it must be especially gratifying to medical men that the first practical application of the new force has been made in the interests of medical art. Demonstrative and satisfactory results of an experimental nature have already been secured in Philadelphia by investigators in the laboratories of the University of Pennsylvania, and the subject has been discussed before a number of the scientific bodies of that city. At a well-attended meeting of the Pathological Society on February 13th Dr. H. W. Cattell described the method and demonstrated its mode of application.

Trained Attendants on the Sick.—A course of instruction consisting of forty lectures, five per week, given by a trained nurse and followed by an examination by a physician has been inaugurated in New York City for the purpose of qualifying trained nurses for the care of feeble elderly persons, little children, chronic cases, and convalescents. Such as pass the examination are allowed to register at the bureau of nurses under the charge of the Medical Society. No pupil will be received under twenty or over forty years of age, unless she has had special previous experience in the care of the sick. References as to character are also required. Besides the class work, each pupil is expected to devote part of the time during the course to nursing in homes of the poor or in hospitals under the supervision of the instructor, as such work gives valuable practical experience and also tests the ability of each pupil. No attendants will be allowed to charge more than \$7 per week during the first year of service. Further particulars may be learned by application, either personally or by letter, to Miss Beck, corresponding secretary, Room 505, United Charities Building, 105 East Twenty-Second Street, or to the members of the executive committee—Mrs. Julius Catlin, chairman, 40 East Twenty-Ninth Street, Dr. Grace Peckham Murray, medical secretary, 25 Madison Avenue, and Dr. E. L. Partridge, medical director.

The Pennsylvania Hospital for the Insane, connected with the Pennsylvania Hospital, is in process of construction and rapidly approaching completion at a cost of about \$50,000—a two-story addition 200 feet long and from 30 to 70 feet wide, with provision for fifty beds. A commodious and well-equipped bath house has also been constructed, which will be utilized for both ordinary purposes and special hydrotherapeutic purposes.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE NEW PHOTOGRAPHY—THE SCHOOL BOARD AND PROFESSIONAL CERTIFICATES—NON-TRAUMATIC ECCHYMOSES—COLLES' LAW—ARTHRITIS DEFORMANS—HEPATIC DISEASE—ARMY SURGEONS—SIR HENRY HALFORD—NOMENCLATURE OF DISEASES—LONDON UNIVERSITY EXAMINERS AGAIN—DIPHTHERIA.

LONDON, February 7, 1896.

THE new photography is creating a sensation in all our medical centres and quite absorbs our conversation. It will doubtless receive the same attention on your side. It is suggested here that, as light is destructive to bacilli, possibly the new penetrating rays may reach the microbes in the body and so give us a powerful ally in our war against disease.

Yesterday afternoon a meeting of medical men was held in the rooms of the Medico-Chirurgical Society to protest against the action of the school board in appointing persons to supervise medical certificates.

A committee was appointed to act in the matter and it is to be hoped the school board will have the grace to rescind its obnoxious regulation.

At the last meeting of the Medico-Chirurgical Society Dr. Lediard read a paper on "Non-Traumatic Ecchymoses," in which he directed attention to the modes of death called asphyxial as well as to conditions associated with ecchymoses in most of the tissues of the body. He held that particular notice of the mucous membrane of the vagina as to its freedom from ecchymoses in asphyxial modes of death was of importance from a medico-legal point of view, as it was probable that this membrane shared with other tissues and organs the liability to such conditions.

Dr. Ogilvie read a paper on the exceptions to Colles' law, of which about twenty cases have been published; they differ a good deal in conclusiveness. These exceptions are certainly rare, but they no doubt exist and their possibility should therefore be taken into account. Mr. Hutchinson held that the law must be accepted and acted upon, though he did not deny the possibility of exceptions. A law of this kind was a relative, not an absolute property. Still our practice should not be altered in consequence of the very rare exceptions, the existence of which all authorities admitted. Dr. Savill thought a *prima-facie* case had been made out for further investigation. Dr. Fox had never met with an exception, and Mr. Cotterell thought no reliable evidence of them had been established. Dr. Lees had never met with an exception and Dr. Coutts said only three supposed instances had been met with at the Shadwell Children's Hospital, besides one doubtful case, which he had himself published. Mr. Parker observed that Colles himself regarded his law as without exceptions. Dr. Ogilvie in reply regretted that he had not quite convinced the president and others, and held that our aim should be to eliminate the possibility of exceptions and each observation in this direction should be weighed rather than counted.

At the Clinical Society meeting on the 24th ult. Mr. Lunn showed a case of arthritis deformans with ankylosis of the jaw on both sides, which he had successfully treated by division of the necks of both condyles and removal of a wedge of bone in a man, aged forty-five, whose trouble began with rheumatic fever twenty-five years previously. For twelve months the patient had been unable to separate his teeth to take solid food. Both his knees were distended with fluid and most of his joints were affected. Mr. Lunn also showed a

case of suppuration of the left shoulder-joint in a man of sixty, with chronic arthritis. The joint was explored with a needle and pus withdrawn; incision was then made, the pus evacuated, the joint explored with the fingers, and a counter-opening made behind. The head of the humerus was found diseased; this was curetted and the joint washed out with hot water. Iodoform emulsion was introduced, the front incision closed, and a small drainage tube left in the posterior wound, but was removed the next day, recovery rapidly ensuing. Six months later recurrence took place and a second operation was performed, since which (June, 1894) the patient has done well, but he now has marked wasting of the muscles about the joint and the movements of the arm are very limited.

Hepatic disease occupied the attention of the Medical Society on the 27th ult., when Dr. Brunton related ten cases illustrating the difficulties of diagnosis, which sometimes amount to impossibility, but he hoped a study of his cases would enable others to avoid some of the mistakes he had made. Mr. Knowsley Thornton followed with an account of cases of hepatic surgery additional to those he had formerly communicated, and some interesting remarks were made by several speakers respecting these two papers.

Sir Redvers Buller distributed the prizes at the army school at Nutley and made a speech which, though recognizing the importance of army surgeons, is not likely to give much satisfaction to them, for he evidently is not more inclined than Lord Wolseley to recognize them as fellow-soldiers. It is curious how the combatant officers should continue to regard themselves as so superior an order to the non-combatants, so-called, who have constantly to incur the same dangers and who have in their ranks so many conspicuous examples of bravery, as is shown by the numbers who have won the Victoria cross.

A memorial brass has been placed in the College of Physicians to commemorate the long presidency of Sir H. Halford. The recently published life of Sir Henry is a very interesting book and contains a number of curious anecdotes illustrating the state of the profession during the long period in which he was its popular head. Copies of the new edition of the nomenclature of diseases were laid on the table at the last meeting of the college.

The examiners of the London University have again committed themselves. This time it is the chemical examiners, who have set a series of questions more fit for technical chemists than for medical students. The questions of experts in the various subjects ought to be submitted to more thorough supervision. Medical students cannot be expected to be experts on every subject. It is clear that the examinations as conducted are unsuitable for the purpose.

Diphtheria still maintains an increased mortality in the returns.

Midwives in Belgium.—The Belgian Gynæcological and Obstetrical Society has recently passed resolutions to the effect that midwives should be placed under the active supervision of a competent authority. It recommends that they should be taught to employ certain specified methods of disinfection and asepsis; to use the thermometer regularly, and summon the doctor when the temperature of the patient remains above 101° F. for more than twenty-four hours; to call in the doctor also as soon as any signs of purulent ophthalmia are noticed in the infant. The strictest precautions are enjoined after attendance on cases of puerperal septicæmia, and it is recommended that any neglect in this respect should be made punishable by law. Any case of puerperal fever must be notified to the proper authority within twenty-four hours.

ROENTGEN'S SHADOW PICTURES OF HANDS AND FOOT.

OUR VIENNA LETTER.

(From our Special Correspondent.)

ROENTGEN'S DISCOVERY—NEW SHADOW PICTURES FOR THE MEDICAL RECORD.

VIENNA, February 12, 1896.

ROENTGEN'S discovery of the permeability to light of certain substances, especially the corporeal soft tissues, continues the subject of investigation and has aroused the greatest expectations as to the possibilities of its further development. Professor Roentgen's announcement comprehended a few facts, the most striking of which was the photography of the living human hand to reveal its skeletal structure. The first photographs exhibited the shadowy outline of the hand with the darker silhouette of the bones. More recently Professor Exner, of Vienna, has shown that irregularities in the density of the solid tissues may be revealed in the photographs by differences in shade, as, for instance in the representation of small bony excrescences or nodules. Whether the so-called Roentgen or "X" rays may be so modified as to reproduce objects of different degrees of transparency, as muscular, vascular, or nervous tissues, is a question entirely beyond present knowledge. The practical application of the discovery is now limited to (1) the conditions of the bones in health or in disease; and (2) the presence of certain foreign bodies or the pathological increase of solid constituents in the tissues.

Among the prominent surgical conditions already subjected to the Roentgen rays for purposes of diagnosis was a case of gunshot wound of the hand, in which the first attempt to remove the ball by incision failed and the second operation after the location of the foreign body by the photograph was easily successful. The outline of the bullet was seen as a rounded projection from the inner border of the metacarpus of the little finger. In the same photograph a sesamoid bone of the thumb was also shown. It was not an unpleasant feature of Professor von Mosetig-Moorhof's jubilee, celebrated on the 1st instant, that he was able to perform successfully several operations under the ægis of the new discovery. An especially interesting case was that of a young woman with a supernumerary phalanx of a toe. The proposed operation was amputation, which was modified by the evidence of the photograph to removal of the superfluous bone, resulting in the restoration of a normal member. Fig. 1 of the accompanying illustrations was taken from this case and shows in addition a deformity of the little toe, which may again stimulate discussion upon the fashion in shoes.

At a recent meeting of the Vienna College of Physicians Kreidl demonstrated Roentgen photographs of the hand of an infant, revealing plainly the diaphyses and the absence of the epiphyses, cartilage being similarly diaphanous with the soft parts (Fig. 2). The opportunity thus offered for the study of rachitis was immediately suggested.

To the courtesy of Professor Exner, who has been active in promoting the practical use of the discovery and to his assistant, Edward Haschek, is your correspondent indebted for the photographs, not previously published, and for an exhibition of the method of procedure. The latter is very simple; in fact, is more easily accomplished than ordinary photography, for the reason that no exposure of the negative is required. A Geissler's or Crooke's tube is placed in the circuit of a strong induced current. Upon making the circuit the tube is filled with a fluorescence reflected from the surface directly opposite the cathodal plate. At about a hand's breadth from this surface in the area of the projected "X" rays is placed the hand or foot or other object to be photographed, upon an or-

dinary plate holder with negative enclosed. The duration of the exposure (?) varies with the effectiveness of the tube, the thickness of the object, and possibly the character of the negative. Professor Exner obtained good results from half-hour exposure of the hand, but for the hand an hour's exposure is safer and for the foot an hour and a half has been required. Satisfactory experiments upon the trunk have not yet been made, but it is thought that results would not follow an exposure of less than five or six hours. It is a necessary condition that the impermeable objects do not fall in identical projections of the "X" rays. The location of a needle or bullet in the hand may be such that in every position it is obscured by the bones.

A suggestion of the further possibilities of the "X" rays has been shown by photographs of gall stones and phosphatic bladder stones in boxes, the earthy concretions giving more distinct outlines than those of organic origin. A photograph has also been obtained of the injected blood-vessels of the hand, which shows little for the discovery beyond the prospect of reproduction of calcareous deposits (Fig. 3).

It thus appears that, although the invisible world is not yet to be revealed to our vision, the new discovery will assume a permanent place in the resources of medicine as a means of diagnosis. The conditions of fractures and dislocations may be definitely established, and for these the discovery has now a practical application. For the study of diseases of the bones, rachitis, osteomalacia, acromegaly, or inflammations and degenerations, an opportunity is offered which may soon be tested. Professor Roentgen is assured lasting fame and reports are daily published of the congratulatory messages and honors conferred upon him, among which has been the public recognition of his services by the physicians of Zurich, where he began his scientific labors.

Starvation Among Paris Physicians.—We learn from the Paris correspondent of the *British Medical Journal* that Dr. Langlard, after fifty years of honorable practice, found no other way of escaping starvation than suicide. It is estimated that there are twenty-five hundred medical men battling with starvation, borne down by heavy rent and taxes. Year by year the number of medical men increases, while, owing to the progress of hygienic science and still more to the disastrous competition of the hospital outpatient rooms and private gratuitous clinics, the number of patients decreases. It is the doctors themselves, says M. Lutaud, who have created their own misfortunes. They have taught lady patronesses of different societies to diagnose diseases, to dress and bandage wounds, to vaccinate their own children and those of their neighbors. Medical science is vulgarized in every way. Doctors write in important daily papers explaining how bronchitis and cramps of the stomach are to be cured, and in fashion journals they teach how to cure pimples and avert headaches. Furthermore, they have urged that hospital treatment be paid at the rate of 4s. 2d. per day; the middle classes profit by this tariff to become hospital patients, their conscience at ease since they pay. Five hundred thousand gratuitous consultations are given yearly in Paris dispensaries, and in this way a large amount of fees is diverted from the medical profession. M. Lutaud includes in his indictment the Associations des Dames, more or less patriotic, which send forth thousands of women who, because they have attended a few medical lectures and walked the hospitals for a few weeks, believe themselves to be something very like doctors and treat their families and friends. This school of medical half-knowledge has been created and kept going by medical men, who are now being crushed by the work of their own hands.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 8, 1896.

GEORGE P. BIGGS, M.D., PRESIDENT.

Addison's Disease.—DR. HENRY P. LOOMIS presented specimens from two cases of Addison's disease admitted to the New York Hospital during his service there. They both presented at autopsy the characteristic lesions of the disease. One had presented the well-known clinical picture with marked pigmentation of the skin; the other had shown no such pigmentation and, with the exception of continued weakness, none of the well-known clinical symptoms. In one the diagnosis had been easily made; in the other, no diagnosis had been hazarded. Both of the patients were men between twenty-five and thirty years of age, foreigners by birth. Both had died suddenly. Both had shown some tuberculous deposits in the lungs. In one case the pulmonary lesion had apparently antedated or coexisted with the changes found in the suprarenal capsules, while in the other the pulmonary tuberculosis had been secondary. The clinical contrast between the two cases and the similarity in the pathological lesions found made them of sufficient interest to warrant placing them on record.

The first case, Angelo M—, twenty-nine years of age, a native of Italy and a worker in mosaic, had been admitted to the hospital with the history of having gradually lost strength during the preceding six months, and of suffering from shortness of breath on slight exertion. He had never suffered from cardiac palpitation, œdema, hemorrhages, or from any pulmonary symptoms. The increasing weakness had prevented him from working any longer. Examination showed the patient to be fairly well nourished, but on slight exertion his fingers would become blue and the heart action feeble. The temperature was about 100° F., the respirations 20, and the pulse between 90 and 110. The urine showed a specific gravity of 1.016, was normal in color, contained no albumin or sugar, but microscopical examination showed the presence of a few hyaline casts. The hæmoglobin was eighty-five per cent., and the number of red blood corpuscles per cm. 3,500,000. As he lay in bed he presented the appearance of a young man in good health; the pulse was feeble, but not irregular or rapid. However, on the slightest exertion the pulse became rapid and somewhat irregular, and this was associated with dyspnoea, vertigo, and cyanosis. Two days after admission, while walking across the ward, he fainted and was revived with difficulty. As repeated and careful examination failed to reveal any organic cardiac lesion, or any blood or kidney complications, and as the patient had no fever or any evidence of active pulmonary processes, it was impossible to make a diagnosis or to account for the ever-present weakness. There was no discoloration of the skin or mucous membranes. Eight days after admission, he was found dead in bed at 11 P.M. An autopsy was made the following day, and both suprarenal capsules were found greatly enlarged, the right measuring 6 by 6 by 3 cm., the left 5 by 5 by 2 cm. The right capsule had become partially embedded in the right lobe of the liver and was closely adherent to it. On opening both organs, they were found to be almost completely converted into a thick, white, cheesy mass presenting all the appearances of tuberculosis. The creamy-colored fluid found in these masses had been examined by Dr. George P. Biggs and found to contain tubercle bacilli. The lungs presented in their upper lobes old tuberculous lesions. The left lobe

contained about a dozen cheesy nodules, each about one-half to one centimetre in diameter, and surrounded by dense pigmented fibrous tissue. In the right lung the lesions were less extensive, and mainly in the form of deeply pigmented cicatrices. There was no evidence of recent extension of the processes. In one of the kidneys, which was otherwise normal, there was found a small nodule one millimetre in diameter, which presented the appearance of a solitary tubercle. The heart weighed seven ounces and showed no gross lesions, although a microscopical examination of the muscle fibres showed them to be quite granular and to contain an occasional fat globule. All the other organs of the body were perfectly normal.

The second case, Morris M—, twenty-six years of age, a Russian rubber-coat maker, was admitted to the hospital with swelling and pain in the lower left abdominal region, accompanied by vomiting and obstinate constipation. He said that his father had died of consumption, and that his own present illness had begun about two years before, at which time he had been in a hospital in Manchester, England. Beginning at this time, there had been a gradual darkening of the skin and gradually increasing weakness, accompanied by shortness of breath and cardiac palpitation. Six weeks before admission to the New York Hospital he had been obliged to stop work on account of weakness. He had suffered from general indefinite pains and headache. Within the last week or two before admission he had had a cough with whitish expectoration and slight fever. He had lost thirty pounds in the last ten months. On examination he was found to be well nourished; there were well-marked areas of bronze discoloration over different portions of the body, especially over the face and neck. The lips and gums were of a bluish-brown color. The urine, amount of hæmoglobin, and the number of red blood corpuscles were all normal. He died fifteen days after admission. At autopsy both suprarenal capsules were found completely replaced by cheesy masses resembling old tuberculous lesions. Both were about the size of a hen's egg and were adherent to surrounding parts. Both lungs were the seat of acute miliary tuberculosis. The kidneys were normal except for a few miliary tubercles. The heart was small but otherwise normal. With these exceptions all the organs were normal.

THE PRESIDENT said, regarding the location of the lesion in these cases, that out of twenty-seven autopsies on children dying of diphtheria there were six in which there were tuberculous lesions in the lungs or other organs, and in two of the six there was tuberculosis of the suprarenals with cheesy degeneration. This seemed to be a rather large proportion. It had occurred to him that possibly in early life the suprarenal capsules were more susceptible to infection with tubercle bacilli, and that probably some of these cases of advanced suprarenal disease found in adults with a few old pulmonary or glandular lesions might have developed in early childhood and the symptoms of Addison's disease only after a long period of time. The proportion in which tuberculosis developed in adults was much smaller than he had observed in children.

DR. R. H. SAYRE exhibited a

Floating Cartilage from a Knee-Joint.—About eighteen months previous to coming under his observation the patient had fallen and injured her knee. After some weeks of rest the swelling had subsided, but for a considerable time she had been unable to use the limb. At the outer side of the patella a small, movable nodule could be felt under the skin, and she complained of pain at this point. He had removed the foreign body by incision. In many other cases he had felt these little bodies in the knee-joint,

but they had caused no inconvenience. It was probable that they caused trouble only after they had become loosened or dislodged by some traumatism. He recalled a case of pain and synovitis immediately following upon leaning the knee on the sharp edge of a window sill. After the subsidence of the swelling, a floating cartilage could be detected in the joint.

DR. W. B. NOYES presented a

Tumor of the Brain, removed from a man whom he had first seen on December 3, 1895. The patient was twenty-five years of age, and four years before had been crushed between two railroad cars, the force being chiefly expended about the lumbar region. After this accident he had remained comatose for four days and had been confined to bed for about two months. There had been no fracture and no paralysis, but since this time he had been in poor health and had presented a number of indefinite nervous symptoms. A year ago he had had an attack of vomiting, associated with failing vision, and a month later there had been an apoplectic attack characterized by blindness, deafness, and paralysis of left arm and of both legs. The paralysis had disappeared in twenty-four hours, but the blindness and deafness had remained. When first seen by the speaker there was moderate spastic paraplegia, exaggerated knee jerk, ankle clonus of both legs, marked ataxia. He was mentally bright, but was fretful and nervous and complained of severe pain in his head, especially in the occipital region. Any sudden jar to his body or head made him complain bitterly. His skin was moderately anæsthetic in most places, but sensation to pin pricking, though much delayed, became very intense after a moderate interval. The region of the body that had been originally injured was hyperæsthetic. He was absolutely deaf in both ears, was very unsteady in his gait, falling to the right when slightly pushed, and his voice was monotonous. The ophthalmoscope showed atrophy of the optic nerve. There was no facial paralysis. He complained of a constriction in his throat, and shortly after coming to the hospital he developed paralysis of the muscles of deglutition. Death occurred suddenly from paralysis of respiration. The diagnosis was brain tumor. The brain was found at autopsy to contain a tumor, an endothelioma growing from the tentorium cerebelli, displacing the entire occipital lobe, cuneus, precuneus, and the fourth and fifth temporal lobes. The growth weighed three hundred grams. It was kidney-shaped, was very hard and nodular, and did not infiltrate the brain tissue. The cord was normal except for slight degeneration of the pyramidal tracts.

DR. JAMES EWING said he had had an opportunity of examining other sections of this tumor than those presented, and he had come to the conclusion that the growth was probably a sarcoma. One of the reasons for this opinion was that in certain places there was a distinct gradation between the ordinary connective tissue and the cells of the tumor; in other places there were many small blood-vessels with well-marked walls and undoubted endothelial cells, not at all resembling those found in the tumor. The gross appearance also seemed to him to be against endothelioma and in favor of sarcoma.

Abnormal Ductus Arteriosus.—DR. WILLIAM VISSMAN exhibited the heart and lungs from a child born at term. After gasping a few times the child had died. It had been delivered by forceps on account of the increasing feebleness of the fetal heart and not because of any difficulty in the labor. On examination it was found that the child weighed six pounds and was nineteen inches long. The scrotum was œdematous, and there was considerable serous fluid in the abdominal, pericardial, and both pleural cavities. The lungs were almost atelectatic. The visceral

layer of the pericardium showed a very large number of small ecchymoses. The ductus arteriosus appeared to be a continuation of the pulmonary artery, and emptied into the aorta. On the right side, there was no pulmonary artery, only a rudiment. Nothing else abnormal was found except that the intercostal arteries branched off from the aorta rather irregularly.

DR. ROWLAND G. FREEMAN presented a specimen of **Atresia Ani** removed from a child dying on the fourth day after birth. It was a male child, and the most marked symptoms had been persistent vomiting and inability to have a movement of the bowels. Examination showed atresia ani. At the autopsy the distention of the abdomen was very marked, and just above the pubes was a large pouch of intestine, almost black, and covered with an exudate. On opening this pouch about two ounces of dark, grumous material escaped. This part of the bowel connected with the anus by a fibrous band about three inches in length. This pouch was surrounded by large clots of blood in the wall of the intestine. A probe passed into the rectum only about half an inch.

Hodgkin's Disease.—DR. JOHN S. ELY presented specimens from a case which had been variously described as lympho-sarcoma, Hodgkin's disease, pseudo-leukæmia, malignant lymphoma, etc. He said that this confusion in the nomenclature in itself indicated a great variety of explanations of the condition and its cause. The specimens were from a woman, fifty-five years of age, a native of Ireland, and a seamstress. She had enjoyed ordinarily good health, but had been intemperate. On October 3, 1895, she presented herself at Bellevue Hospital, stating that for three weeks previously she had had some pain in the upper part of the back and abdomen, in the left hip and thigh, and had also had a slight cough with scanty white expectoration. Physical examination showed dulness over the right lung with some pleuritic crackles. The heart was normal in position and action. The liver was much enlarged, extending from the fifth rib to one inch below the umbilicus. It was hard and its surface rather smooth, except on the lower border, where it was uneven. The spleen appeared to be somewhat enlarged. Six days after admission a little clear serum was drawn from the right pleural cavity. On November 2d she became delirious, on the next day she developed slight jaundice, and she died on November 6th. During her stay in the hospital there had been a moderate fever, the temperature ranging between 99° and 100° F. up to the morning of November 5th, when it reached 101.8° F. The treatment was stimulant and laxative. The autopsy was made about thirty-six hours after death. The woman was emaciated and slightly jaundiced; there were old pleuritic adhesions on the right side; the heart was slightly enlarged; there was a pericardial thickening anteriorly about two centimetres in diameter; there were atheroma and some old thickening of the endocardium. The left lung was emphysematous and œdematous, and there was a small quantity of muco-pus in the bronchi. The bladder was normal. The uterus contained some bloody liquid. The rectum was normal. The appendix contained a hard, irregular body surrounded by inspissated feces, but there was no evidence whatever of inflammation. The stomach was normal. The pancreas was rather hard but normal. The liver weighed nine pounds four ounces. There were about two ounces of bile in the gall bladder; the duct was pervious. The color of the liver was yellowish-green, and it was abundantly mottled with small, whitish nodules, and toward the free border with a number of reddish nodules which were rather soft and closely resembled small cavernous angiomas. In addition to these, in the right lobe there was a large cavernous angioma measuring three by

four by two and a half inches in diameter, and having a fibrous core. The left lobe was much smaller than the right; its free border was very thin and presented the appearance of an old contracted cirrhosis. The posterior mediastinum and upper mesenteric lymph nodes were greatly enlarged, and many of these masses were softened in the centre and were two inches in diameter. The enlargement of the posterior mediastinal glands was particularly marked on the right side, and they encroached to a considerable extent on the right lung at its base. The spleen was slightly enlarged, of a deep red color, and the trabeculae were thickened. The left kidney was slightly enlarged, its capsule slightly adherent, and studded with cysts. The kidney was rather hard, pale, cortex thin, and markings indistinct. The right kidney showed the same lesions, but the cysts were smaller. The suprarenal capsules were mottled and yellowish in the centre. The microscopical examination of the liver and of these various nodules showed them to consist almost entirely of small spheroidal cells similar to the lymphoid cells of the lymph nodes. In many of the lymph nodes themselves was a large amount of fine granular degeneration which under a low power resembled the cheesy matter of tuberculosis, but which when examined more carefully resembled anæmic necrotic tissue. In the liver the small spheroidal cells were collected in small nodules—the lighter spots. They appeared to have originated in the blood-vessels of the liver. In the channels of the cavernous angioma were to be seen a large number of these spheroidal cells, sometimes in considerable masses. There was also a rather diffuse infiltration of the liver with these spheroidal cells. The small spheroidal cells in the spleen were decidedly increased in number. In many of the reddish nodules in the liver were to be found collections of these spheroidal cells, and also necrosis and hemorrhage. These reddish nodules were therefore not cavernous angiomas, but masses of small spheroidal cells which had undergone degeneration and in which some hemorrhage had occurred. The intestine and stomach showed no enlargement of the lymph nodes, although the upper mesenteric lymph nodes were much enlarged. The lesion, therefore, in this case was confined to the posterior mediastinal glands, the lungs, and the liver.

The speaker said that in March, 1888, Dr. Hodenpyl had presented to the society an interesting specimen of this condition, in which the intestine was the principal site of the enlargement of the lymph nodes. On comparing the two specimens it was evident that the changes were quite similar, except that in the case just presented there was degeneration, which did not occur in the former case.

In general, it might be said that the condition was of short duration and was frequently accompanied by fever. The masses did not encroach upon the surrounding tissues as tumors did, but there was simply a dilatation of the channels in which the cells accumulated. Flechsner had written an exhaustive article on this subject in 1893 and had expressed the belief that the process was due to some form of infection, basing his opinion on the large amount of necrosis, the presence of fever, and the fact that the cells were those ordinarily found in the lymph nodes but which had been stimulated into inordinate growth. The appearances were certainly not those of sarcoma, the speaker said, and hence it was improper to speak of it as a lympho-sarcoma. It was much more likely that the condition was an inordinate multiplication of the elements of the reticulum and the cells of fatty tissue, and possibly an intoxication of the system by some unknown substance. It was worthy of note that the lymph nodes first affected were the mediastinal lymph nodes, those of the neck, or those of the intes-

tine or mesentery—in other words, well-recognized channels of infection.

DR. WARREN COLEMAN said that Flechsner had referred to certain bodies among the cells, which stained with hæmatoxylin and eosin and which he considered parasitic. He would like to ask whether these had been found in the case just reported.

DR. ELY replied that he had seen these bodies, and they had seemed to him to be fragments of nuclei or cells rather than parasites.

THE PRESIDENT said that he had seen a very similar case recently, occurring, however, in a boy of twelve years. In this case it was noticeable that the duration of the disease had been at least two years. The first development had been a mass of glands in the axilla, and these had been removed. A few months later he had returned to the hospital with enlargement of the inguinal glands. He had next developed marked ascites. There had been no recurrence in the axilla. The autopsy showed the glandular enlargement to be limited to the glands of the groin, pelvis, and mesentery. The liver presented the appearance of an old syphilitic cirrhosis rather than the nodular involvement described in the case under discussion. In the centre of some of the enlarged glands was a hard, whitish tissue, looking somewhat like tumor tissue. In this case there had been almost constant fever.

DR. T. M. PRUDDEN said that he did not think we would come to a better understanding of these pathological changes which resembled each other so closely until we knew a good deal more about the blood. It also seemed to him that very carefully recorded morphological work must be done. If sarcoma meant anything, it meant a connective-tissue growth, and hence one must find out whether there was a stroma occurring with these growths or whether simple collections of spheroidal cells. Again, if it were hyperplasia, one must determine whether the reticulum had also grown along with these cells, else it was not a hyperplasia.

The society then went into executive session.

Some General Statistics.—The 72 races inhabiting the world communicate with each other in 3,004 different tongues, and confess to about 1,000 religions. The number of men and women is very nearly equal, the average longevity of both sexes being only thirty-eight years, about one-third of the population dying before the age of seventeen. Moreover, according to the most careful computation, only 1 person in 100,000 of both sexes attains the age of one hundred years, and only 6 to 7 in 100 the age of sixty. The total population of the earth is estimated at about 1,200 million souls, of whom 35,214,000 die annually—*i.e.*, an average of 98,848 a day, 4,020 an hour, and 67 a minute. The annual number of births, on the other hand, is estimated at 36,792,000—*i.e.*, an average of 100,800 a day, 4,200 an hour, and 70 a minute.

Generally, taking the entire world, married people live longer than single, and those who have to work hard for their living longer than those who do not, while also the average rate of longevity is higher among civilized than uncivilized races. Further, people of large physique live longer than those of small, but those of middle size beat both.

The Micro-Organism of Scurvy, isolated from the gum, staining in aniline and resisting Gram's stain; rendering gelatin fluid; its cultures producing fever in guinea-pigs and rabbits, and being a diplococcus differing from any usually present in the mouth, has been found by Testi and Beri.—*Gaz. deg. Osped.*, August 10, 1895.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 17, 1896.

S. B. W. McLEOD, M.D., AFTERWARD JOSEPH E. JANVRIN, M.D., IN THE CHAIR.

Address of the Retiring President.—DR. McLEOD, in his retiring address, gave a retrospect of the work of the society. During the seven years that he had been a member of the executive committee, ex officio or otherwise, the membership had increased from 250 to 1,050. Eighty-four medical colleges in every part of the world were represented. The attendance on the meetings had averaged 90, and had occasionally reached 210 and over. Dr. McLeod said he highly appreciated the honor of having been repeatedly elected to preside over the association. He then introduced his successor, Dr. Joseph E. Janvrin.

Address of the President-Elect.—DR. JANVRIN thanked the society for the honor which it had conferred upon him, and said he would do all he could as presiding officer to further its interests. He then read his address, entitled

The Ultimate Results, in my own Experience, of Vaginal Hysterectomy for Cancer Originating in the Cervix Uteri.—The number of cases in one man's practice must, of course, be limited. Among cases of cancer of the uterus which had come under his care and on which he had performed hysterectomy, there were sixteen in which the disease had originated in the cervix. He had been led to analyze these with relation to the ultimate results from the fact that at a recent meeting of the New York Obstetrical Society doubt had been expressed whether the results of hysterectomy for cancer originating in or involving the cervix justified the operation. He had then stated that his own results had been such as not only to encourage hysterectomy, but to absolutely demand it, for he believed that there had been non-recurrence in about seventy-five per cent. of the cases.

The 16 cases were differentiated as follows: 5 in which the cervix alone was involved, 4 in which the cervix and upper part of the vagina were involved, and 7 in which the cervix and uterine body were implicated. Twelve of the 16 were operated upon prior to November, 1892, the first in 1884, the twelfth in 1892. Of these 12 cases, which dated back more than three years, 3 died within four days succeeding the operation, 1 of them from shock and 2 from septicaemia. They were among his early cases, and death was attributable to his inexperience with the operation. Of the remaining 9, recurrence took place in 2, 1 dying within about sixteen months, the other within eighteen months after the operation. Three were lost sight of after six months or a year, but up to that time had had no relapse. The remaining 4 were all seen and examined at least three and a quarter years subsequent to the operation, and were well. Of the 4 cases operated upon since 1892, 1 was operated upon twenty-two months ago, the other 3 in the fall of 1895. All were free from recurrence except one of the more recent ones, in which at the time of operation he recognized his inability to remove all of the disease.

Dr. Janvrin quoted his paper published in the MEDICAL RECORD in 1892, with regard to involvement of the vagina simply by attrition, and expressed the belief that if this portion were excised early, along with the uterus, such cases could be cured. Four of his successful cases had been of this kind. If there were thickening of the broad ligaments without history of prior pelvic inflammation, it was probably cancerous, and hysterectomy, either vaginal or suprapubic, would be useless: if there were a history of

past attacks of pelvic inflammation, and absence of cancerous cachexia, it was his custom to operate. His results had been sufficiently good to justify him in continuing in this course.

In no case of vaginal hysterectomy had Dr. Janvrin injured a ureter. In two he had had vesico-vaginal fistula, which became apparent after some days and was due, he thought, to too tight packing with gauze.

Recurrence the Rule.—DR. W. T. LUSK said he had seen a good many cases of cancer of the body of the uterus where the results of hysterectomy had been satisfactory, but in all of his own cases in which the disease had been limited to the cervix it had only been a question of time as to when recurrence had taken place. Nor had he ever been able to obtain anything definite on this point until Dr. Janvrin had read his paper to-night. In conversation Dr. Jacobs had admitted that his results had not been good, and Dr. Thornton had said that he had returned to the Schroeder operation, but supposed that he would only be regarded as an old fogey and was surprised to learn that Dr. Lusk had also returned to the Schroeder operation. After hearing Dr. Janvrin's experience he might try total extirpation again, with new hope.

DR. H. J. BOLDT congratulated the president upon his results. They certainly were better than those of most operators, probably all operators. Permanent cure of malignant disease of the cervix was comparatively rare. In his experience there was frequently a continuance of the malignant disease after hysterectomy for cauliflower growth of the cervix, shown by manifestations as early as the third or fourth month. He thought malignant disease of the cervix would continue to give less favorable ultimate results than malignant disease of the body of the organ. But much depended upon the mode of operating, and his opinion to-day was that the galvano-cautery used by Dr. Byrne, or the Paquelin cautery, was preferable to the knife and scissors. Dr. Janvrin had been fortunate in injuring the ureter in no instance, for the accident had occurred at the hands of many, two or three times with Dr. Boldt.

DR. GEORGE T. HARRISON thought it was one of the grandest triumphs of modern gynecology that the uterus, the seat of carcinomatous infiltration, could be removed with such excellent results. The mortality of the operation itself had been reduced to nine per cent., and the percentage of cases without recurrence after five years had been in his own practice, so far as he could learn, seventeen per cent. But the percentage of ultimate recoveries should be greater, for there could be no doubt that cancer in the beginning was purely local, and complete removal should effect a cure. An earlier diagnosis would greatly increase the favorable results.

Three Conditions of Success.—DR. A. P. DUDLEY thought the results of removal of the uterus for cancer depended upon three conditions: 1, The age of the patient; 2, the form of the disease; 3, the manner in which it was attacked. He was unable to give his own statistics, but believed the average time of return was eighteen months or two years, and he did not think this average would be reduced greatly unless cases were seen earlier. The method of operating would depend upon the skill of the operator and the size of the vagina, etc. He had tried the different methods, but at present doubted the propriety of leaving a large granulating surface. He would try now to close the wound by suture and obtain primary union.

Henry Durrant, the founder of the Geneva Red Cross Society, is now, it is reported, at the age of sixty-seven, in great poverty and nearly starving. He spent all he had in promoting the society.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 20, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Amendment to the By-Laws.—Section 5 of the by-laws was amended to read: "No fellow whose annual dues remain unpaid shall be entitled to a vote or be eligible for office."

The Recent Progress of Treatment in Affections of the Upper Respiratory Tract.—The meeting was held under the auspices of the section on laryngology, Dr. James E. Newcomb, chairman. Three papers on divisions of the above subject were read and discussed.

(a) **Nose and Accessory Sinuses.**—DR. F. H. BOSWORTH briefly reviewed recent progress of treatment in affections of the nose and accessory sinuses. In a paper fifteen years ago he had said: "I do not believe any physician, I care not what his abilities may be or how much wisdom and skill his management of these cases may have endowed him with, is justified in promising to cure any given case of nasal catarrh of long standing." He was gratified now to be able to review the advances made since that time.

In the author's opinion Carl Koller's discovery of the use of cocaine in 1884 constituted the most important advance. He referred not alone to its anæsthetic property, but also to its power to deplete the vessels. In 1885 Dr. Bosworth read a paper in which he claimed that the amount of moisture in the expiratory air in excess of that in the inspiratory air was derived chiefly from the turbinated tissues, and not from the mucous membrane of the lower respiratory passages, as had been claimed up to that date. The correctness of this view had since been demonstrated by physiological experiment. It enables us to eliminate the old and indefinite term catarrh, which was based on the idea that the disease resulted in excessive secretion. Better information had shown that there was interference with this respiratory function, and the indications for treatment were its restoration instead of checking it, as by burning away some fungous growth supposed to be present. Tunnelling a passage through the nose and sacrificing whatever tissues might be encountered we learned to regard as absolutely unjustifiable. If there was true hypertrophy, we recognized that the object of treatment was to reduce the inflammation rather than to destroy tissue which was endowed with physiological function. The nasal septum, however, had no special function so far as he knew, and if it were an obstruction it should be removed.

Growing out of the idea that in catarrh there was excessive discharge came the notion that the nose was an excreting organ. We had learned how false this view was. The secretions of the nose were entirely bland and never offensive *per se*, but they might become so in syphilitic disease, etc. When purulent it was usually due to disease in the accessory sinuses and constituted an empyema.

Dr. Bosworth still adhered to the belief that any form of nasal necrosis was in nearly every instance an expression of a constitutional disease and not the result of a local inflammatory trouble. In numerous autopsies Zuckerkandel had found no necrosis of the ethmoid cells. In ethmoidal disease pus usually drained into the antrum, rarely into the sphenoidal or frontal sinuses. The indications were to open up the cavity which contained pus and irrigate.

Progress was evident in the fact that we had established a definite class of diseases, definite diagnosis, and carried out treatment with definite clinical indications. We heard less of reflex neuroses than formerly, because we had learned to recognize many

affections to be directly symptomatic of diseases rather than reflex. We did not cure asthma by treating the nose, but by curing any nasal trouble we helped toward a cure of the asthma.

DR. MORRIS J. ASCH opened the discussion on this paper. While, as Dr. Bosworth had said, cocaine had been of great value, it had two important drawbacks—danger of cocaine habit and of leading to secondary hemorrhage. While there had been much advance in the treatment of disease of the accessory sinuses, yet, as the author had said, most of these cases were obscure and it was doubtful whether even the most skilful could always make a diagnosis, and great care should be taken lest treatment result in injury. In disease of the maxillary sinus, for instance, puncture through the inferior meatus might not prove so simple and might even be dangerous.

DR. ROBERT C. MYLES regarded cocaine as a necessity in accurate diagnosis. While the nose might supply the greatest amount of moisture in healthy breathing, there could be no doubt but what many persons breathed mostly through the mouth, and that therefore the mucous membrane below the nose was capable of performing this function if called upon to do it. He thought modern physiologists ought to take up the subject and test this respiratory function more fully. He thought Dr. Bosworth's view that the nasal septum was not a physiological factor was open to question. Its mucous membrane had many glands, and it ought not to be cut away *ad libitum*. Rather than remove the whole of the vomer, it was far better to take away a part of the inferior turbinated, for in time its tissue would be so far replaced as to supply all necessary moisture. Dr. Myles thought we had made important advances in the treatment of the accessory sinuses through the aid of the lamp, trocar, irrigation, etc. In disease of the frontal sinuses he often found the ethmoid cells softened, not necessarily necrosed. On cleaning out the cavities he found that the cells returned to a healthy state.

DR. GLEITSMANN had found difficulty in entering the antrum of Highmore until he witnessed puncture through the lower meatus by Schmidt, of London. In nearly all instances this method was easy and enabled one to wash out the antrum in disease of that cavity.

DR. BOSWORTH said he had not seen a case of cocaine habit which was worse than the chewing-gum habit. The mucous glands of the septum only moistened the membrane as every mucous membrane was kept moist by such glands, but the function of the turbinated tissues was different, being that of serous exosmosis to moisten the inspired air and modify its temperature.

(b) **Naso-Pharynx, Oro-Pharynx, and Laryngo-Pharynx.**—DR. JAMES E. NEWCOMB read a paper on the progress of treatment of these cavities. The general statement could be made that the treatment of diseases of the pharynx had kept pace with that of the nose and larynx. Regarding anæsthetics aside from cocaine, in this country the preference was given to ether and chloroform, in England to nitrous oxide; in France bromide of ethyl had been commended highly. The advantages of the latter had been summarized as follows: Rapidity of action, short period of excitement, complete analgesia with preservation of the mental faculties, rapidity of recovery, unirritating vapor, relative absence of unpleasant effects. Disadvantages: Hypersecretion, unavailable for operations at all prolonged, comparatively unstable compound; if inhaled too long it might cause muscular contraction. Antipyrin was now used in combination with cocaine to prolong and intensify the effects of the latter; the bleeding was also diminished. Recently guaiacol in olive oil had been suggested as a means of producing local anæsthesia.

Nothing specially new was to be said regarding means of removing lymphoid hypertrophies from the naso-pharynx. Dr. Hopkins thought they were liable to recur. The necessity for local disinfection in the presence of lesions had been clearly shown, for there was constant exposure to microbic infection. In local tuberculosis surgery was indicated, although in exceptional cases it was thought to be followed by rapid pulmonary tuberculosis. Naso-pharyngeal tumors had been removed with success by electricity, but in case of recurrence surgery should be resorted to. It had been claimed that electrolysis succeeded in about sixty per cent. of the cases. In malignant disease erysipelatous injections had proven of benefit in certain cases. Dental caries and the rheumatic and gouty diathesis favored the development of the leptothrix. Treatment should be by salicylic acid, corrosive sublimate solution, etc., and puncture of hypertrophic lacunæ by electrode.

Treatment of enlarged tonsils in patients under sixteen years of age consisted in removal by some form of guillotine, except in bleeders or in those whose tonsil was too flat. In older persons the cold and hot snare and forceps were at our disposal. The galvanocautery snare had come to be used much more frequently during the last few years.

Acute inflammations of the pharynx and tonsil were now regarded as nearly always of infectious origin. The bacillus coli commune was more apt to produce a chronic amygdalitis than an acute attack. The proper treatment of such forms of tonsillitis seemed to be scooping out crypts, followed by iodine solution. Any one of a large number of antiseptic solutions would often shorten the attack. In recurrent suppuration of the tonsil search for possible foreign body embedded in the tissue should be made. In initial tonsillar inflammation salol was of value, but after abscess had formed it was useless and surgery was demanded. We should not wait for the abscess to point.

Bromide of Ethyl for Anæsthesia.—DR. GLEITS-MANN had found bromide of ethyl a valuable anæsthetic for short operations. Antipyrin had also proven valuable as a local injection in pain or to prevent pain during operation. Parachlorphenol in glycerin had been recommended to subdue pain, and he had found it useful in some cases, while it failed in others.

(c) **Larynx and Trachea.**—DR. D. BRYSON DELAVAN read a paper on recent progress of treatment in affections of the larynx and trachea. Intubation for the relief of acute laryngeal stenosis had long since become an established success, and treatment of chronic stenosis by this method was growing steadily in favor. Pachyderma laryngea had recently been studied, and it had been proven that the redundant tissue could be removed by the electrolytic method, best applied by means of a bipolar instrument, the needle being inserted into the growth under anæsthesia, with a current of fifteen milliamperes for five minutes. Much had been written concerning the etiology of laryngeal œdema, but the statements were conflicting. In papillomatous growths of the larynx the repeated spray of absolute alcohol had in two cases caused complete disappearance, and the method deserved a trial since surgical removal was so often followed by recurrence. Carcinoma of the larynx was not amenable to treatment by toxin injections, and Dr. Delavan gave considerable space to its surgical treatment. This consisted in thyrotomy or complete or incomplete laryngectomy. In this connection the work of Cohen, Wagner, Butlin, and others was mentioned.

No disease of the larynx had received more attention recently than tuberculosis and many suggestions had been made for its cure, but one with much experience must feel that most of them would prove delu-

sive. Yet patients had been known to recover either through change of climate or local applications. Lactic acid was one of the local applications which had proven beneficial, and Chappell had had good results from injections of creosote into the diseased laryngeal tissue. Krause was among those who recommended surgical treatment.

DR. ROBERT ABBE spoke on the surgical treatment of cancer of the larynx. His first operation was easy, but subsequent experience taught him that laryngectomy might in any case prove a most difficult and dangerous operation, and it should never be undertaken by an amateur surgeon. As in cancer of the tongue, partial removal, leaving glandular enlargements, offered little hope so far as cure or much prolongation of life was concerned. Dr. Abbe related the case of a boy in whom repeated removal of papillomatous growth of the larynx had been followed by recurrence, and he thought of trying Thiersch skin grafts applied to the base. Regarding tracheal surgery, in one case of obstruction he opened the trachea, but as dyspnoea continued, and having no silver tube at hand, he introduced a rubber tube down the trachea, which immediately gave relief. It was then learned that the obstruction was due to an aneurysmal tumor, which burst and caused death two days later.

DR. W. F. CHAPPELL mentioned removal of the vocal cord in bilateral paralysis, which he and Dr. A. H. Smith had practised in one case by a forceps devised for the purpose. Nor had anything been said about applications to papillomatous growth of the vocal cord through the tracheotomy wound, a method by which he had cured one case. English surgeons had also reported cases. In laryngeal tuberculosis no one method could claim all the beneficial results. He had cured two cases in three weeks by creosote applications. If there were extensive pulmonary complication, of course only palliation could be expected. There were two forms, acute and chronic. Attention should be given to climate, rest, food, and hygiene.

SECTION ON GENERAL MEDICINE.

Stated Meeting, February 18, 1896.

W. H. PORTER, M.D., CHAIRMAN.

R. W. WILCOX, M.D., was elected chairman for the ensuing year and Louis Faugères Bishop, secretary.

Syphilis as a Factor in Diseases of the Heart and Lungs.—DR. LEONARD WEBER read the paper on this subject, giving a number of clinical histories to show that syphilis performed an important part in diseases of the heart and lungs. The first case was that of a patient thirty-eight years of age, suffering from chronic catarrh, cough, and muco-purulent expectoration. There was tenderness over the sternum and at times there were dyspeptic troubles. Twelve years before he had had syphilis. The diagnosis of chronic bronchial catarrh with syphilitic infiltration of the trachea was made, and the patient was put on the protoiodide of mercury for one month with no effect. He was then put on potassium iodide, beginning with fifteen grains and increasing to three drachms a day, and was practically cured. The second case was a merchant who gave the appearance of emphysema, with some pressure symptoms in the mediastinal region and headaches. He was put on the protoiodide of mercury and began to get better. The third case was in a man twenty-eight years of age, who had had syphilis two years before. Contrary to advice he married. His wife was healthy, but the first child died at the age of three months of convulsions; the second child was living but unhealthy. The man died of tuberculosis; his

wife now had tuberculosis and was affected by syphilis. The fourth case was in a man who had had syphilis, but no serious constitutional symptoms. He complained of dry cough, his heart was enlarged, and his pulse was irregular. The iodides did not agree and were discontinued. He died at the age of sixty, and autopsy showed a bovine fatty heart, atheromatous arteries, enlarged liver, and the ascending colon adherent at the hepatic flexure. The fifth case was in a man fifty-eight years of age who had had gonorrhœa at nineteen, afterward a syphilitic sore, which was not followed by characteristic symptoms that he noticed. He married, had no children, lived a quiet, moral life, but after the age of forty complained of a tired heart. There were no false sounds and the pulse was regular. He was put on potassium iodide and improved.

The sixth case was in a woman forty-six years of age. She was healthy when married at eighteen. Her husband had had syphilis. She gave birth to a seven months' fetus and had trouble with her lung. Examination showed an indurated inflammatory condition of the upper lobe, but no phthisis. She recovered under the proper treatment and five years later had no signs of lung trouble, but was not the vigorous, healthy woman she had been. She again married and again aborted. She afterward developed signs of heart trouble, slight vesical paresis, and weak, irregular pulse. The iodides did no good and mercurial treatment was impossible on account of the condition of the kidneys.

Dr. Weber said that aside from the evil after-effect of syphilis in producing bronchitis, etc., he thought the destructive influence upon the heart muscle as well as upon the arteries was far greater than was generally thought. The entire system was affected by syphilis and the resisting power of the tissues was diminished. It was, therefore, erroneous to look upon syphilis as a mild disease, even when properly treated. By continuing the treatment in after-years the effects of the poison might be kept in abeyance.

In discussing Dr. Weber's paper Dr. W. H. THOMSON said that in private practice he thought cardiac syphilitic disease was common, while pulmonary syphilitic disease was very uncommon. He had had one case of pulmonary syphilitic disease in which he had made a lucky hit in diagnosis. A gentleman came to him with the history of cough, emaciation, and hæmoptysis. A prominent physician had diagnosed the case as tuberculosis. Nothing was found at the apex of the lung except a little bronchitis, but upon percussion there was a peculiar leathery sound over the middle lobe without any corresponding murmurs. There were also scattering patches at the base of the lung much like broncho-pneumonia. The man had had syphilis four years before with various manifestations afterward. A favorable prognosis was given, the man was put on specific treatment, and he began to gain in flesh and improve in color. Later he went to the physician who had told him he had tuberculosis and asked him to examine his lungs. The doctor said he did not have tuberculosis and never had had. The patient then reminded him of the time when he had examined his lungs before and told him he did have consumption and would soon die from it.

Dr. Thomson said he thought there was great difficulty in telling a case of syphilitic disease of the lung, for it might be fibroid in character and could not be diagnosed from fibroid pneumonia. The presence of the tubercle bacillus made the differentiation of tuberculosis from syphilitic disease of the lung comparatively easy.

But syphilitic heart disease was not at all uncommon nor was syphilitic endarteritis, but how was one to be differentiated from the other? This might be

done by careful examination of the arterial and capillary condition. In cardiac failure from syphilis the pulse might be weak, but no valvular disorders and perhaps nothing but the weak, irregular, or intermittent action of the heart would be observed. Syphilis affected the arteries but not the arterioles and capillaries, as general endarteritis did. He had illustrated this to a class a few days ago by two cases, both with anginal pains, failing hearts, and apparently the same conditions; but on scratching the skin of one of them with the finger nail a bright streak appeared, showing that the capillaries and arterioles were not affected, while no amount of rubbing produced any change in the other man's skin, for there was general endarteritis interfering with the cutaneous capillary circulation.

Dr. Thomson said he thought ten per cent. of the cases of heart failure in men after the age of forty might be due to syphilis.

In the treatment of syphilitic heart disease he agreed with Dr. Weber that potassium iodide was of great value, but he had obtained the best results from the use of the mercurial vapor bath. He believed the mercurial vapor bath was the best treatment for all the later results of syphilis except neuroses, in the treatment of which he still adhered to the injection of corrosive sublimate.

Dr. BISHOP said that while he was at St. Luke's Hospital a man was admitted to the tuberculosis wards whose condition was diagnosed as syphilitic disease of the lungs by the absence of the tubercle bacilli and presence of other lesions.

Dr. WEBER said he was glad to hear the strong points made by Dr. Thomson and agreed that syphilitic disease of the lung was not so common as that of the heart. The point of differential diagnosis from disturbed peripheral circulation was a valuable one. He had obtained good results from the mercurial vapor bath, but of late years had had as good results from the inunction.

The Treatment of the Indigestion of Starchy Foods.—Dr. REYNOLD W. WILCOX read a paper on this subject. He said that to treat this condition properly one must carefully consider its etiology. Such indigestion was often due to the habit of partaking freely of fluids along with starchy food, yet it was sometimes difficult to persuade persons to desist from this practice on account of the thirst and discomfort which they experienced. Dr. L. D. Bulkley, of New York, had recently offered a most excellent practical solution of this difficulty. It was to direct the patient to partake freely of hot water about half an hour before meals. This he had found would effectually quench the thirst. Too great gastric acidity was also unfavorable to the proper conversion of starch. Such acidity could be combated by the use of sodium bicarbonate, and it was now known that even the prolonged administration of this salt in large doses exerted no harmful influence. He had obtained good results from the administration of normal phosphate of sodium with bicarbonate of sodium on rising in the morning. In patients afflicted with indigestion of starchy foods, constipation often alternated with diarrhœa. This diarrhœa should not be treated with opium or the usual intestinal astringents, but by the use of intestinal antiseptics. Among the most useful of this class was bismuth naphthalate, in doses of ten or fifteen grains, in powder or capsules after meals. Various methods of coating pancreatin pills had been suggested, so that they might pass safely through the stomach and begin their action in the intestine. One of the best coatings, that suggested by Dr. W. H. Flint, consisted of an alcoholic solution of shellac containing a little tolu to make the coating sufficiently elastic. The solid malt extracts were useful adjuvants to treatment, but most of the liquid extracts

contained such a large proportion of alcohol as to seriously interfere with their power to convert starch. He had used with considerable satisfaction a Japanese preparation of diastase. In one case, however, after its administration the patient became faint and exhibited symptoms somewhat like those of belladonna poisoning. As the use of the remedy in this instance was not repeated, he could not, of course, say how much of this sudden disturbance was directly attributable to it.

In discussing Dr. Wilcox's paper DR. QUIMBY said he thought there was a good deal of truth in the old saying in the New England hills that false teeth and spruce gum were good for indigestion. Why then did organic chemistry teach that the saliva must be taken at the time of the food? He did not wish to seem to question science, but experience proved that the acidity of the gastric juice could be much diminished by the action of the saliva. Science would lead to the belief that pancreatin did not pass through the stomach unchanged and it seemed that it should not, but nevertheless he had gotten excellent results from its use in certain conditions.

DR. ANDREW H. SMITH said he would like to ask the ground for preference for sodium bicarbonate to other alkalies. He used the hydrated magnesium in the form of milk of magnesium, a smaller amount of which would neutralize the acidity than of the other. It was also free from the objection of disengaging gas, and it acted as a mild laxative. Dr. Quimby's remark as to the use of the saliva brought up a point that could be easily verified. When he had been hard at work he had often suffered from heartburn, which he could relieve by simply working the jaws and swallowing the saliva, thus avoiding the trouble of getting medicine.

DR. BURALL said he had read a short time ago an article in which the writer suggested the use of small articles in the mouth for exciting salivary secretion and urged it as an original suggestion. He thought there was often a nervous irritation in these diseases and one of the great difficulties was the arranging of the environments of the patient so as to carry out treatment. Many led sedentary lives, some ate too fast, and the physician had to make up with drugs what the patient lacked in himself. For the nervous element he found strychnine of service. Occasionally a little ipecac could be added to stimulate the liver.

DR. WILCOX said Dr. Quimby was right, and he had been amused at the fact mentioned by Dr. W. G. Thompson in his book on dietetics that well-fitting false teeth were of service. There was no doubt much of the acidity of the stomach could be relieved by swallowing saliva. The reason he used the sodium bicarbonate was because he had gotten into the habit, but it was probable that it increased the amount of mucus in the stomach. No doubt some cases were relieved by pancreatin, but the main reliance must be put upon the stomach.

Military Surgery.—Many of the soldiers of our army are now supplied with a little packet made up of silk coated with rubber, and containing sublimate-gauze, cambric, and triangular bandages, with a couple of safety-pins. On each triangular bandage are a number of pictures showing how it may be applied to almost any part of the body. With the improved sighting of the new rifle, however, in connection with the modern projectile, a marksman can kill his man at two miles, and at two thousand yards the projectile will pass through three human bodies. A field-cannon having a calibre of three inches and firing a projectile similar to this small one is effective at a distance of eight miles.—PARKE.

Surgical Suggestions.

Dilatation of Urethra.—A large percentage of female patients suffering with subacute vesical symptoms, such as painful micturition, bearing-down sensation, and a feeling that the bladder is not emptied after micturition, can be readily relieved by dilatation of the urethra. The greatest amount of practical good that has been obtained in bladder troubles by the use of the cystoscope may be attributed to the dilatation necessary to the introduction of the instrument.—BALDY.

Facial Paralysis.—1. Facial paralysis usually attributed to cold is frequently caused by mild otitis media. 2. This otitis is due to a pharyngo-rhinitis. 3. The aural origin of facial paralysis accounts for a number of symptoms not otherwise easily explained—pain, etc. 4. The prognostic significance of this etiological fact is very great, for usually facial paralysis of aural origin is readily cured.—LAUNOIS, *Ann. des Mal. de l'Oreille et du Larynx*.

Frost Bites.—

R Ichthyol,
Resorcin,
Tannic acid.....ãã 1.00
Water..... 5.00

M. Apply with a brush at night.

Should this, for one reason or other, be objectionable, the following formula may be substituted:

R Resorcin.....2.00
Mucilage of gum arabic,
Water.....ãã 5.00
Powdered talc.....1.00

M. Apply topically with a brush.

—BOECK.

Amputations.—I have always held that a circular skin flap, with or without a lateral incision, as the emergency may demand, is the ideal flap, the muscles being divided an inch or more above the level of the circular incision through the skin, and the bone sawed on a level with the muscle. Dissection of the periosteum from the end of the bone in order to secure a periosteal flap is entirely unnecessary and should not be done.—WYETH.

Tumors.—Every tumor first noticed in the breast after the thirty-eight years' epoch is, in the great majority of cases, primarily malignant; in the remainder it is certain, sooner or later, to become associated with malignant features in one form or another.—SNOW.

Ectopic Gestation.—It is stated that the symptoms of ectopic gestation are: A relative period of sterility, associated frequently with a history of precedent disease of the pelvic organs; amenorrhœa; enlargement of the uterus, the sympathetic disturbances from the side of the stomach, and changes in the breasts; irregular hemorrhages and "colicky" pains; the presence of a tumor to one or another side or behind the uterus.—GRANDIN.

Children in Moribund Women.—Wait until the mother dies and then extract the child as quickly as possible. Four hundred and sixty-nine Cæsarean sections have been done post mortem, producing 363 dead and 112 living children. Probably the majority of the dead children succumbed shortly before the mother died.—REMY.

Aneurism.—Hydrated calcium chloride in doses of about a drachm a day, in conjunction with rest and other suitable adjuvant measures.—COHEN.

Furunculosis.—Extract of colchicum, in doses of from 2 to 4 cgm. (gr. $\frac{1}{3}$ to gr. $\frac{2}{3}$), in conjunction with topical applications of spirit of camphor.—BROCK.

New Instruments.

KNIFE FOR TONSILLAR ADHESIONS.

By BEAMAN DOUGLASS, M.D.,

ASSISTANT SURGEON AND PATHOLOGIST, MANHATTAN EYE, EAR, AND THROAT HOSPITAL; INSTRUCTOR, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE accompanying illustration shows a tonsil knife made by the Ford Surgical Instrument Company, of New York, after a pattern submitted by me. The instrument is $7\frac{3}{8}$ inches long, $3\frac{1}{2}$ inches being the handle, $3\frac{7}{8}$ inches a delicate shank. The cutting part is placed at an angle of 45° with the shank, the blade being $\frac{1}{2}$ inch long, probe pointed, $\frac{1}{16}$ inch broad, and the cutting edge curved. The blade is notched near the probe-pointed end on the cutting surface. The instrument is made of steel in one piece.

Its uses are (1) to sever adhesions of the tonsil and anterior pillar of the fauces and (2) to incise crypts in the tonsil. Many cases of recurrent tonsillitis, of peritonsillar abscess (quinsy sore throat), and of hypertrophy of the tonsillar tissue are due to these small bands of adhesions uniting the anterior faucial pillar and the tonsillar mucous membrane. These bands of adhesion may be small and single, or they may be generally united, forming a coalescence of the faucial pillar and the anterior tonsillar surface and behind this a pocket in which food, pus, epithelium, or decomposing material may collect as a nidus for infection or inflammation. If the adhesions are distinct, taking only the form of a band, they may then cause tonsillar irritation by the dragging to which the tonsil is subjected and by the pus which can collect behind it. If this irritation continues there results an hypertrophy of the tonsil; if it is inconstant at the times of irritation, a tonsillitis or pharyngitis localized about the adhesion or a peritonsillar abscess.

All tonsillotomies, whatever the method employed, should be preceded by an exploration to ascertain if such adhesions exist, which if present, are to be separated before tonsillotomy. If this point is neglected we may fail to remove enough of the tonsil, or may cut the pillar of the fauces.

Many a case of hypertrophied tonsil will be cured by simply separating the adhesions, and the major operation be avoided.

In enlarged crypts of the tonsil filled with foul-smelling caseous material, this knife can be introduced to the bottom of the crypt and the pocket incised to its base for drainage.

Its operation is simple. After cocaine, four per cent., has anesthetized the parts, the probe knife is used to find and then to cut the adhesion by introducing it between the tonsil and the anterior pillar and drawing it forward and inward to the edge of the pillar. If the adhesion is narrow and band-like it is readily severed; if it is broad and helps to form the wall of a pocket the knife can be introduced, the probe point pushed through the tissue and the adhesion cut, and then re-introduced until the entire depth of the pocket is incised. The after-treatment consists in keeping the raw surfaces apart until they are healed, and this is best accomplished by touching the raw edges with a solution of nitrate of silver, forty grains to the ounce.

123 EAST THIRTY-SIXTH STREET, NEW YORK CITY.

Doctors of Philosophy.—During the academic year 1894-95 the University of Leipzig granted the Ph.D. degree to one hundred and sixty-three candidates.

A NEW POCKET SPOON FOR HYPODERMATIC INJECTIONS.

By DICKSON L. MOORE, M.D.,

COLUMBUS, OHIO.

My excuse for this instrument will be evident to every man who uses hypodermatic medication in private practice. The desirability of cleanliness in this work is apparent; practically it is hard to attain. Because the physician who drops a tablet into the barrel of his syringe filled with water brought in by a member of the family from he knows not where—because this man seldom or never has abscesses following injection wounds, there is no reason why he should not use a sterile injection if he may. The difficulty of boiling water for injection in the bowl of an ordinary spoon, the greater difficulty of afterward balancing the spoon with its blackened, heated bowl upon a table while the contents are being sucked into the syringe, are reasons, together with others equally forcible, why many physicians who in greater things observe surgical cleanliness in this smallest of operations violate all principles of asepsis.

This consideration and that of increased convenience have led me to devise this pocket spoon, here shown in its exact size.

It is made of aluminium, and when closed can be easily carried in the vest pocket or in the case of an ordinary hypodermic syringe; when open it stands firmly enough to require no support.

The quantity of water desired is drawn into the syringe and is then thrown into the bowl, which holds just thirty minims. A match held beneath the bowl

causes the water to boil in a few seconds. A tablet dissolves readily in the heated water. It is then redrawn into the syringe and is ready for use. This injection is certainly safer than if unboiled and the convenience of preparing it is not a small consideration.

When folded, the bowl B is brought back over the upright C. The base A, which has an inverted bowl corresponding to B, is then brought back over B and covers the blackened lower surface of the bowl.

It has been made for me by the Columbus Pharmaceutical Company.

A NEW HEMOSTATIC CLAMP.

By HOWARD CRUTCHER, M.D.,

CHICAGO.

THE one feature that distinguishes this clamp is the absolute reliability of its lock, which is very simple and which the illustration shows quite clearly. The shanks are serrated, and the sliding link can be adjusted so as to include any amount of tissue. I devised this clamp especially for use in hysterectomy, in which the notorious inefficiency of the ordinary lock has been amply demonstrated. To tie the handles

with silk is tedious and unsurgical. This lock can also be used for many other instruments, especially the large tumor volsella.

These clamps are supplied by Messrs. Sharp & Smith, Chicago, to whom I am indebted for the courtesy of the accompanying illustration.

103 STATE STREET.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 22, 1896:

	Cases.	Deaths.

Typhoid fever.....	12	4
Scarlet fever.....	127	13
Cerebro-spinal meningitis.....	2	2
Measles.....	479	20
Diphtheria.....	245	32
Small-pox.....	0	0

The Non-Existence of Human Equality.—Dr. Forbes Winslow contends that under despotic forms of government suicide is much less prevalent than it is in countries governed on the principles of republicanism, which is another term for human equality (*The Annals of Hygiene*). Where the actions, thoughts, lives of human beings are controlled rather by others than by themselves, where the life of the masses is, so to speak, regulated by the logical intelligence of constituted authority rather than by the oft-times erratic impulse of the individual, under such conditions (paradoxical as it may seem until explained) life is in itself more pleasant to the individual, and he is hence less anxious to terminate it. It seems to us logical to infer that each act of self-destruction must necessarily imply that the person so acting has no wish for a continued life, and it must be conceded that this frame of mind must be the outcome or the result of a life so lived that its living has not been, or at least is not at the time of the act, a pleasure to the individual. Even an insane man will not kill himself if his insanity is a pleasure to him; the very act of self-destruction implies a determination to destroy a consciousness that is a constant or a momentary source of discomfort. We assume as incontrovertible that no healthy person whose life, whose very living, is a source of pleasure ever committed suicide, ever wilfully sacrificed that which to him was

a pleasant possession, and when we find self-destruction most prevalent among those whose lives are self-regulated, we are compelled to pause and ask whether each individual is capable of regulating his life, his methods of life, to the best advantage, to the attainment of the best ends of which his organism is capable. In his lecture on "Liberty of Man, Woman, and Child," Col. Robert G. Ingersoll contends that thought is material, that thought is a brain product, as vegetables are products of the soil, and that each individual should harvest his mental crop and act in accordance with the dictates thereof. The idea is in

accord with the theory of human equality; but it is not in accord with the teachings of biology or of physiology, the student of which cannot logically believe in the equality of mankind. Nature plainly indicates that she intends that a comparatively few shall lead the masses who are designed as followers. Grains from the same ear of corn planted, in the one instance, in the rich, fertile soil of Pennsylvania, and in the other instance in the barren, sandy soil of lower Jersey, will germinate and produce crops in both localities, but how vastly will they differ; so the same exciting or inciting impression upon the brains of one thousand men will produce one thousand crops of thoughts, but how vastly will they differ, from the most logical to the depths of absurdity, from conservatism to socialism, from good citizenship to nihilism, from self-preservation to self-destruction. While, according to our constitution, man may be born free and equal in the eyes of the law, he is not free and he is not equal in the eyes of nature; he is born a slave to inherited tendencies, and he is born in all varying degrees of self-capacity. Did we but recognize the unquestionable fact that mentality is capable of development, not alone by books and by the help of others, but by exercise and use of the mental attributes born with each of us; did we each one of us recognize that we are not all equal in the eyes of nature, and did we each strive patiently to understand and properly estimate ourselves and to fit ourselves into the holes designed for us by nature, we would have very little anarchism; we would have much less self-destruction, and this world would be altogether a much more pleasant place to live in. Argue as we may, men are not all equal, physically and mentally; nor are women either, and it is the direct and indirect and remote results of the assumption that they are that make most of the trouble of the world.

Longevity and Activity.—Great men usually carry their full mental vigor and activity into old age—M. Chevreul, M. de Lesseps, Gladstone, and Bismarck are evidences of this anthropological fact. Pius IX., although living in tempestuous times, reached a great age in full possession of all his faculties, and the dramatist Crebillon composed his last dramatic piece at ninety-four, while Michel Angelo was still composing his great canvases at ninety-eight, and Titian at ninety still painted with all the vigor of his earlier years. The Austrian General Melas was still in the saddle and active at eighty, and would have probably won Marengo but for the inopportune arrival of Desaix. The Venetian Doge Henry Dandolo, born in the beginning of the eleventh century, who lost his eyesight when a young man while on an embassy to Constantinople through the treachery of the Greek Emperor Manuel, was nevertheless subsequently raised to the highest office in the republic, managed successfully to conduct various wars, and at the advanced age of eighty-three, in alliance with the French, besieged and captured Constantinople. Fontenelle was as gay-spirited at ninety-eight as in his fortieth year, and the philosopher Newton worked

away at his tasks at the age of eighty-three with the same ardor that animated his physical prime. Cornaro was as happy at ninety as at fifty, and in far better health at the age of ninety-five than he had enjoyed at thirty. These cases all tend to show the value and benefits to be derived from an actively cultivated brain in making a long life one of comfort and of usefulness to its owner. The brain and spirits need never grow old, even if our bodies will insist on getting rickety and in falling by the wayside, but an abstemious life will even drag that old body along to centenarian limits in a tolerable state of preservation and usefulness. The foregoing list can be lengthened out with an indefinite number of names, but it is sufficiently long to show what good spirits and an active brain will do to lighten up the weight of old age. When we contemplate the Doge Dandolo at eighty-three animating his troops from the deck of his galley, and the brave old blind king of Bohemia falling in the thickest of the fray at Crecy, it would seem as if there was no excuse for either physical, mental, or moral decrepitude short of the age of four-score and ten.—*National Popular Review*.

Unprincipled Speculating Specialists.—Dr. L. A. Tourtellot, of Utica, N. Y., in a letter from Nice to the *Utica Observer*, says: "A large number of invalids are sent to the Riviera every year, and this leads me to notice an abuse not unknown in America but which prevails to a far greater degree in Great Britain and on the Continent. It is that of a type of medical specialism which has lately been denounced in the strongest terms by the leading reviews, magazines, and newspapers in London and Paris as little better than an organized robbery of the sick in mind and body. The most noted of these specialists in the great capitals of Europe are known as consultants, chiefly, and by them invalids are sent, with unquestioned authority, to one of several hundred health-resorts on the Continent, where they are handed over to the local specialist, who remits a handsome fee to the consultant and proceeds to amuse and fleece his poor patient as long as possible. Finally, when hope and purse are alike exhausted, he is sent to another confederate, probably in another country, where a new diagnosis is made and a new treatment prescribed. This course is repeated until at last the patient, bankrupt in health and in pocket, is ordered home to die."

Alcoholic Neuritis in Old Age.—In a recent number of *Brain* Dr. Maude publishes a brief account of a most interesting case. The patient, who was a robust country gentleman of sporting habits and used to an out-of-door life, had taken stimulants in considerable excess for at last twenty years. Even eighteen years ago no unusual daily allowance was half a gallon of beer, a bottle of sherry, and eight or ten liqueur glasses of "neat" whiskey. His favorite drink was beer, and even in the summer of 1894, although over seventy-five years of age, he would often consume two quarts of beer, a bottle of sherry, and half a bottle of whiskey in a day. He had had no serious illness, except broken bones from riding accidents and a fractured humerus at the age of seventy-three from a fall downstairs one evening after dinner. During the year 1894 his great muscular power became much impaired, and toward the end of the year he began to complain of severe darting pains in the left lower limb. A few weeks later the hands and feet began to swell rather suddenly, the skin became thin and glossy, while there were small ecchymoses over it. A similar condition was present on the insteps of both feet, while the calves and thighs were oedematous and the muscles shrunken. The knee-jerk could not be elicited, and the pupils were small and did not react to light. The heart sounds were somewhat feeble, but they were regular

and there was no sign of dilatation. Without any previous marked change in his symptoms he died suddenly after a few minutes' dyspnoea about two months after the onset of the symptoms. Dr. Maude considers the case to have been one of peripheral neuritis, and directs attention to several interesting points, such as the advanced age of the patient, the excess of his alcoholic indulgence, and the absence of mental change; the fact also that he was essentially a beer drinker is interesting, with reference especially to the views of the late Dr. James Ross as to the kind of alcoholic beverage most likely to produce neuritis.—*The Lancet*, October 19, 1895.

Phthisis in Australia.—Dr. G. L. Mullins, of Sydney, has contributed to the *Australasian Medical Gazette* a paper on the prevalence and distribution of phthisis in the Australian colonies. He controverts the statement of Hirsch that "the reputation that Australia used to enjoy for the rarity of consumption and for the favorable influence of its climate upon the course of the malady has of late been shown to be a mistaken one." Comparing the death rate from phthisis both per 100 deaths from all causes and per 1,000 living inhabitants of Australia with other countries, Dr. Mullins shows that Australia has by far the lowest rate, and that the capital cities of that continent have a much lower rate than European cities. Further, it appears that phthisis is decreasing in prevalence in Australia. From the returns of Queensland—the only colony from which suitable returns can be procured—it appears that the Australian-born population is not subject to phthisis. At the last meeting of the New South Wales Branch of the British Medical Association Dr. Sydney Jones advocated the establishment of a "farm hospital" for the treatment of cases of phthisis in its early stage. The buildings should be of an inexpensive kind, surrounded by a large area of land to be cultivated by the patients, and in this way it might be partially self-supporting. He objected to the mixing of early and advanced cases of phthisis in the same hospital.

Cholera in Germany in 1894.—In all 1,004 cases of cholera occurred between May 23d and the middle of December, 1894, in the German empire, out of which 490 ended fatally. These figures, taking the population of the empire at its official estimate of 49,429,470, represent a mortality from cholera equal to 0.1 per 10,000.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

EXPERIMENTAL LESIONS PRODUCED BY THE ACTION OF RICIN ON THE CORTICAL NERVE CELL OF THE GUINEA-PIG'S AND RABBIT'S BRAIN—THE EFFECT OF ACUTE RICIN POISONING.¹

(Preliminary Paper.)

BY HENRY J. BERKLEY, M.D.,
BALTIMORE.

Literature.—The amplification of our knowledge of the minute anatomy of the nervous system has taken such tremendous strides during the past few years that an insight into the recent advances has already become widely known, not only among those who make an especial study of this branch of anatomy, but to every one interested in the progress of the science of medicine.

This increased accuracy in our information has been owing almost entirely to the chromate of silver method introduced by Golgi and his followers, aided in a measure by the vital methylene blue stain of Erlich.

Information concerning the pathological changes in the central nervous system, more particularly in the cortex of the cerebrum, has not, however, kept pace with the study of its histology. Experimental research, only by which can an accurate understanding of human pathological lesions be drawn, has not been accurately followed, and to-day we stand at a point not greatly advanced over that at the opening of this decennary. Especially is this true of the cerebral lesions induced by infectious diseases, where changes are supposed, but their character remains almost unknown.

The one great reason for the lack of progress in this direction has been owing to the few stains from which any accurate return could be expected. It is true that methods have again and again been devised, only to be discarded within a few years as untrustworthy; and by which two observers could seldom see the same structural lesions. Two different and entirely opposite methods that were first used for histological purposes have lately claimed considerable attention. The method of Nissl offers a field for study that is in a measure accurate and reliable, but the variety of cellular changes shown by it are oftentimes difficult of interpretation, though the main objection is that, while it allows of a fair view of the protoplasm of the body of the nerve cell, the distal portions of the cell, the dendrites and their appendages, are invisible, and likewise the important axis cylinder remains untinged.

The other method, the silver stain, while it impregnates all portions of the neuron, has many objections. The nerve elements are not certainly stained and it permits little information to be gathered of the variations in the structure of the protoplasm. Investiga-

tors with the Golgi method have all been hampered by the infrequency and imperfect staining of the nerve elements in adult tissues, and the general difficulties attending the examination of human pathological material, as well as by the absence of knowledge of post-mortem changes likely to be met with in these specimens.

I believe the first application of the Golgi silver method in pathology was made by Kronthal in 1887¹ on a brain from a case of general paresis, and as his results did not seem to be encouraging, the further use of the method appears to have been abandoned for the time. In 1892-93 in the course of other work I made several attempts to study the brains of alcoholics and parietic demented, but with indefinite and unsatisfactory results.

During 1893 Greppin² renewed the attempt to discover definite lesions in the brains of parietics, but also with imperfect issue.

During 1894 several memorials on similar subjects appeared. Colella³ studied the cerebra in several cases of general paralysis and alcoholic psychoses with somewhat better success, in that he found well-defined changes both in the dendrons and axons of the cells, that were in part afterward substantiated by other observers; the alterations being mainly in the form of tumefactions of these portions of the neuron.

Next in order follows the now well-known work of Golgi⁴ on the pathology of experimental rabies. Here the prevailing lesions were on the same order as those seen by Colella in paresis, namely, a varicose condition of the axons and neurons; but extend further, for Golgi finds and depicts atrophic degenerations in the corpora of the nerve cells.

Following the article of Golgi came one by Klippel and Azoulay⁵ on the alterations of general paralysis, the lesions found being of the same character as those previously determined by Colella, but their interpretation of the tumefactions of the dendrites, when they describe that the first stage of the process consists of an abrasion of the spines (gemmulæ) covering the protoplasmic expansions, then an agglutination of many spines to form irregular bands of protoplasm, and finally a coalescence of these drops to form larger ones upon the dendritic stem, is certainly erroneous, for, as we shall presently see, the gemmulæ have no part in the process beyond rapid atrophic changes.

In the fall of the same year appeared the contribution of Andriezen⁶ entitled "Newer Aspects of the Pathology of Insanity," in which there is a short paragraph on the lesions in alcoholic insanity, where a process analogous to that mentioned by Colella and Klippel is figured and described, but Andriezen finds much greater implication of the corpora of the cells than the former writers.

This short sketch of the literature finishes all the pathological work up to the beginning of the present year, and it will be observed, includes only one experimental study.

¹ Read before the Philadelphia Pathological Society, December 12, 1895.

In March, 1895, Monti, of Pavia,¹ published a monograph on the changes found in the cerebral cells after the induction of artificial embolism by the injection into the carotid artery of dogs of lycopodium or carbon powder. The results obtained were exceedingly interesting and instructive, and the drawings accompanying the paper were made with greater care and accuracy than in any of his predecessors' works.

Briefly, he finds after the injection of the powder, that after an interval of at least five hours has elapsed, there begins in the protoplasmic extensions of the nerve cells an alteration limited to the divisions that come off from the main stems at some distance from the cell body, the amount and intensity of the pathological alteration depending on the length of time after the injection. There may be in these cases only a lesion manifest in the branch or branches turned toward the site of the nearest embolism, while in others, more clearly within the area in which the blood supply has been cut off, complete implication of every extension of the cell is seen. The changes in the earlier instances consist of an irregular swelling of the protoplasmic substance of the dendrite, and commence always at the distal extremity of the cell and proceed toward the centre. The axon is involved only after the degeneration of the cell's corpus. Monti applies the name "varicose atrophy" to this peculiar condition.

Quite as interesting as the preceding study is another by the same writer on the alterations produced in the central nervous system by starvation.² Though the lesions of the nerve dendrons are on a somewhat different order than those before described, they yet bear the same imprint. The cerebral cells show great thinning of all the dendrons of the involved cells; very small varicose enlargements form along both apical and basal dendrites without implication of the cell body or axon.

The last article completes the entire literature on the pathology of the several morbid conditions as has been seen with the chrome-silver methods, besides my own investigations, which have been accomplished by a somewhat different stain, and comprise experimental studies on chronic alcoholism in the rabbit, poisoning from the serum of one animal injected into the blood of another, rabies, the present study on ricin poisoning, and some work on the pathology of mental diseases, part of which have been published and part remain incomplete.

Substantially we have found lesions of the nerve-cell structures in the form of parenchymatous degeneration, both of the protoplasmic extensions and corpora of the cells, but no involvement of the axis cylinder except in unusual instances, and this in all the morbid processes studied.

One point we would call attention to before closing this portion of the paper: the fact that, no matter how extensive and diffused the destruction may be among the cells of the cortex, a number of the elements remain histologically sound, which would seem to indicate that certain neurons of a brain rind have a higher degree of resistance to destructive influences than their fellows, and this fact is not without its importance in the consideration of mental diseases, especially those caused by the poisonous products of certain pathogenic bacteria.

I should also state that none of my work has been done with the ordinary rapid Golgi method, which we have found entirely unsuitable and unreliable with adult tissue, but with the silver phospho-molybdate method, which offers greater advantages both in the fineness of details and certainty of staining over the other.

While the study of lesions of the nervous system by silver methods has thus laid open a number of pathological conditions, work has not been entirely wanting in the experimental field by the Nissl methods. Time does not permit me to go into details, and I would refer those interested to the recent articles of Sarbo¹ and Dehio;² also to the work now being done in Nissl's laboratory on cell changes following the extirpation of muscles.³

The two articles by Monti above referred to, are the only ones bearing on the subject that have appeared since the publication of my article on the condition of the nerve cell in serum poisoning. In all of these different morbid states there is sufficient variety in the form and general deportment of the tumefactions, as well as in the relations of the gemmulæ to the swellings, to enable an accurate observer to differentiate in a slide, without great difficulty, from which pathological condition it was prepared.

A further consideration of the gemmulæ may not be out of place at this point and have a future bearing on the pathological conditions hereinafter described. Monti, who gives in his last article the first detailed notice of the buds I have found, designates them as spines and describes them as having the appearance of a bunch of moss covering the protoplasmic stems, and mentions that they are constantly found on the cells of the adult brain, the latter statement agreeing with what I have already determined.

In slides prepared according to the long Golgi method, we have not been able to determine them with any constancy, and even with the ordinary osmium-bichromate mixture of Cajal they are apt to be inconstant, at least in my experience. By the silver phospho-molybdate method they are constantly stained, are of fixed shape according to the variety of cell from which they proceed, and are present in every kind of cell of the cerebrum and cerebellum in varying numbers, but reach their highest development on the psychical and Purkinje cells.

Opportunity has not been afforded me to study their development after the beginning of extra-uterine life, but, judging from the works of others, they do not seem to be present on the ganglion cells of the cortex until some time after birth, certainly some weeks in the lower animals (Van Gehuchten et al.). They are present on the protoplasmic prolongations of the psychical cells of all vertebrates (Cajal), but their deportment and expansion depend greatly on the animal from which the section was taken. Generally speaking, they are less prominent in the lower vertebrates and reach their highest development in man. Even in the human being their numbers and luxuriance depend on the individual, for in persons of low mental grade they are not nearly so prominent as in better endowed persons.

Their development appears to depend greatly on the receptivity of the species of animal to education from external impressions, dull vertebrates like rana presenting a wide difference from animals capable of receiving a higher education, as the dog. Hence we are inclined to believe that there are inherent qualities in the development of the cerebral cells themselves that render one species of animal more susceptible of receiving and retaining impressions from extraneous sources than others—in other terms, they have memory for past events, and not only is the quality of the protoplasm different in one animal from another, but there are differences in the actual anatomical construction of the neuron. Each psychical cell of the cortex possesses an individuality of its own, the forms and general appearance of the cells differ widely, the

general arrangement of the principal dendrites is varied, the disposition of the gemmulæ varies slightly between each cell, the apical protoplasmic extensions are sometimes widespreading, sometimes do not expand into a number of branches until they reach the neighborhood of important nerve endings in certain well-defined regions of the brain rind.

A more extensive examination of histological specimens leads us to reopen and reconsider the question whether the nodosities on the dendrites are normal or artifacts from the deposit of fine precipitate on the dendrons, giving them the appearance of being covered with swellings, as is the view held by Flatau.¹

In early post-fœtal life the dendrites are covered with varicose swellings that may persist over a variable period. In some adult animals these varicosities seem entirely to disappear (man, rabbit), while in others they still persist, though in very inconsiderable numbers (guinea-pig). Even when they are present in these animals they are always of small size, present rather the appearance of irregularities than varicosities along the finest stems, and are covered, equally with the other portions of the branches, with the gemmulæ, and never encroach upon the thicker portions of the primordial or basal dendrites. That they are not precipitate is further evidenced by the fact already mentioned in a previous article, that under intense illumination they show none of the appearance of precipitate, but fine parallel lines converging on the unswollen portions of the dendrons. Differences in the staining qualities of the cells are much more puzzling than any deposit of precipitate, and accordingly may lead to wrong interpretations. Post-mortem changes may be rigidly excluded, as all our tissues were perfectly fresh.

Hitherto we have also had the absence of the gemmules to guide us in determining whether we were dealing with a normal or an abnormal swelling. In the present investigation, especially in those animals that died after a few hours of the intoxication, the gemmulæ are often found to be present, but to counterbalance this loss of control we find in the cases of pathological swelling the lateral buds are pushed further apart from each other than is natural. This is, however, only in the earliest changes, while in further advanced stems they gradually disappear, until, when the thicker primordial dendrite becomes involved in the tumefaction, and this is never the case in normal preparations, they disappear entirely. This retention of the gemmules on the swollen stems is a strong argument against the tumefactions being artifacts, as it clearly shows that the swelling comes from within the substance of the stem and pushes the gemmulæ, which are still adherent, outward and apart.

The researches upon ricin, the amorphous poison obtained from the castor bean, made by Erlich and Flexner, have induced me to infer that this agent would be an excellent one to produce pathological alterations in the protoplasm of the ganglionic nerve cells.

I cite in abridgment the lesions discovered by Dr. Flexner in his acute cases, in tissues other than the nervous system: "In the lymphatic glands there are hemorrhages, many of the elements are necrotic, and fragmentation of the nuclei is common. The lymphatic apparatus of the intestines shows in an analogous manner the destructive influence of the poison, but cell death is more extensive. The spleen shows changes similar to the lymph glands, and these are localized in part in the Malpighian bodies. The liver presents the greatest variety of cellular death. In the capillaries the endothelial cells are sometimes fragmented and necrotic, and the leucocytes suffer a

similar change. But in the liver cells the process reaches its height. There are foci of coagulation necrosis in which some of the cells are preserved, but they are hyaline in appearance and devoid of nuclei, while in others the cells are much altered in appearance and staining properties and the nuclei have undergone another form of necrosis. They have died as a whole, becoming paler and paler until they finally refuse to stain. These foci of necrosis are surrounded by large quantities of granular detritus. The lymphatics are also choked with nuclear detritus."

We obtained the brains from six of the acute cases of Dr. Flexner, and after hardening them carefully in Müller's fluid, further treated them according to the silver phospho-molybdate method, and used for control purposes the fresh brains of a healthy rabbit and a guinea-pig treated according to the same procedure as the pathological material.

The intensity of the destruction of the nerve elements was found not to depend entirely upon the amount of the poison injected into the system of the animal, but also upon the duration of the poisoning. Almost equal changes can be produced in seventy-two hours by the inoculation of .125 milligram ricin, as by the inoculation of a whole milligram extending over a period of only thirty-six hours, and perhaps had the animal survived a still longer time the lesions would have been even more profound.

The Effects of the Toxin Acting Directly upon the Substance of the Protoplasm of the Nerve Cell—

(a) *Lesions Seen with Nuclear Stains.*—The study of the two selected cases (Nos. 4 and 6) for examination of the blood channel's walls with nuclear dyes shows lesions entirely similar to those found by Flexner in the abdominal organs. In the finer vessels there are many places in which the endothelial nuclei are swollen, receive the stain badly or not at all, and are occasionally fragmented and necrotic. The perivascular channels contain considerable quantities of a grained detritus that does not take up any other dye than eosin, and this only in sufficient amount to give it a pale rose tint. This detritus is to be found in the spaces around all the medium-sized and larger blood-vessels, and the amount of it is in places sufficient to retard the lymph currents. All evidences of the presence of thrombi in the smaller vessels are absent.

The protoplasmic bodies of many of the nerve cells appear to be unaffected by the poison, a few are seen to be breaking up into granular matter. Very curious nucleolar figures are to be found everywhere in the nerve cells of the gray substance. The fine, dust-like granules and the two or three larger particles normally present in the ganglion cells are no longer to be found, but in their place in the interior of the nuclear ring lies a brightly stained, irregular mass, sometimes of horseshoe outline, at others of varied shapes, composed of the aggregations of the nucleoli and the nucleolar dust.

(b) *Lesions Seen with the Silver Phospho-Molybdate Method.*—Our six cases divide themselves, so far as the intensity of the destructive influences determined by the drug are concerned, into two principal groups: Those in which the pathological alterations are limited to the finer branches of the cell, that is, when there obtain fine swellings of the outermost portions of the protoplasm of the neuron accompanied by little denudation of the gemmulæ, and the remaining portions of the cell are free from injury; and, secondly, cases in which there is involvement of the dendrites down to the cellular body, with great disappearance of the lateral buds, and some involvement of the corpus of the cell. The first detail is to be found after the continued action of the drug over comparatively short periods of time; the second either after the

¹ Arch. f. Mik. Anat., Bd. 44.

long-continued action of such small doses of the toxic substance as will enable the animal to survive a certain number of hours, or, after throwing into the circulation of a (proportionately to the weight of the animal) very considerable amount of the poison, inducing a sudden and intense destructive action upon the cerebral cells.

All the varieties of cells in the cortex are equally influenced by the poison, but as the pyramidal cells

FIG. 1.—Projection cell from the second layer of the cortex showing an increased number of pathological swellings on the finer stems of the cell. There is now distinct diminution of the gemmule wherever the swellings are found. Subcutaneous injection of 0.25 mgm. ricin, death in 48 hours.

FIG. 2.—Projection cell showing numbers of large swellings on the apical dendrite, thinning of the protoplasm of the stem in the intervals between the nodules, and considerable loss of the gemmules along the margin. Ricin poisoning of 72 hours' duration, injection of 0.125 mgm. ricin.

FIG. 3.—Long apical-process pyramidal cell with extensive swellings, chiefly fusiform in character, along the trunk, with entire destruction of the lateral branches and very great atrophy of the lateral buds. Ricin poisoning of 12 hours' duration, intravenous inoculation of 1 mgm. ricin.

are the most equally stained and best defined our description applies mainly to them.

We find in the first class on the tips of the dendrons, particularly those situated within the molecular layer, well-defined, rounded, irregular, and fusiform swellings, which begin toward the extreme outer endings of the protoplasm, and gradually extend downward (Fig. 1). On these tumefactions the gemmules may or may not be involved. When the swelling is comparatively fresh, the gemmule do not seem to be greatly diminished in numbers, but when it is older they disappear. The gemmule are pushed apart and undergo a change which is not well defined by the silver impregnations. They absorb less of the staining matter, are yellowish in color instead of black, and before any other well-defined alteration takes place they fall off from the stem, their detritus is taken up by the lymph currents, and they vanish entirely. As the diameter of the gemmules does not exceed one-tenth that of a red-blood corpuscle, it is quite easy to understand that they may be very rapidly removed by the lymphatic apparatus and quickly disappear.

In the earlier stages there is little atrophy of the stem in the intervals between the swellings, the gemmule are retained in but slightly diminished numbers and show only occasional variations in their staining. The thicker dendrites are in this class rarely if ever involved, nor does the cell body lose any of its definite sharpness of outline, or appear swollen or malformed. The basal dendrites seldom participate to any extent

in the first steps of the degenerative process. One is occasionally seen with a small swelling along the course of one of the branches, but this is exceptional.

No lesions of the axons from the pyramidal cells, or other nerve fibres of local or extraneous origin, are ever to be found; likewise neuroglia changes are equally absent.

In the cerebellum the Purkinje cells are involved equally with the pyramidal in the cerebrum, only fewer of them are damaged to any extent. The basket and other cells with their peculiar axons show the same alterations of their dendrons, but the nerve extension is always normal. The Bergman support cells and the rayed neuroglia cells are natural.

The changes found in the nerve cells in the second class of cases are relatively much more interesting, from the greater intensity of the alterations found as well as in the absolute pathological significance they possess. It is always to be remembered, though, that except in one case (No. 6), there is nothing approaching an involvement of all the neurons of the cortex, but that there is actually a large proportion of cells in all regions of the layers that have every indication of health, and, while very extensive lesions are found in many of the neurons, those that are normal and those that belong to the first class greatly outnumber them.

In every section taken from Cases IV., V., and VI., we see numerous pictures corresponding to Fig. 2 and Fig. 3. Practically the neuron is reduced to the main apical dendrite, with sometimes a few of the basal ones remaining intact, sometimes degenerated. The apical dendrite is shorn entirely of its lateral branches or they are reduced to irregular filaments: the outspreading uppermost branches have vanished completely; the tree-like form has departed, and it is reduced to a trunk ill shapen and knotted, and its roots are dying.

Along the stem of the trunk we find swellings of various shapes and sizes with, in the intervals between the swollen portions, lines of protoplasm much thinner than in the control specimens at corresponding points. When we look for the gemmule we find they are still present in some places, in others they are entirely absent; but as a whole their numbers are greatly

FIGS. 4, 5, 6.—Large pyramidal cells from the second layer of the cortex in advanced stages of degeneration. Ricin poisoning of 12 hours' duration, intravenous inoculation.

diminished and the remaining ones oftentimes appear to be badly stained.

Turning from these middle forms to others that have suffered more considerably in the atrophic pro-

cess, we find an extensive reduction in the length of the apical and basal dendrites. Some of these are thinned to a great degree, but have few tumefactions, but others have numerous swellings of all sizes, both in the apical and basal dendrites, the primitive ones always showing the greater degree of tumefaction and atrophy (Figs. 4 to 7). There is still retention of very limited numbers of gemmulæ. Often there is entire absence of them over certain of the stems, which now appear thinned to fine lines with the remains of a nodule showing at intervals upon them.

In the most degenerated type the basal dendrites are reduced to stumps; the primitive one is atrophied down to near the body of the cell (Figs. 6, 7), is mainly formed of a few large tumefactions irregular in shape, and the gemmulæ have entirely vanished. The corpus of the cell, previously angular, is now seen as a rounded body with imperfect dendrites extending from it, but there is as yet no breaking up of the substance of the cell. The destruction of the receptive function of such a cell must be complete.

This concludes the description of all the positive lesions of the neuron from the effects of ricin poisoning, the nerve fibres of different kinds not being affected.

Alterations of the neuroglia, on the other hand, demand more than a passing attention. In the last three cases the staining of the support elements is equal to any in the control preparations. Apart from the peculiar local cells along the pial margin there is but one kind of neuroglia cell stained in either white or gray tissues, and this is the so-called mossy vascular cell. I do not consider this absence of the star-rayed cells as important, having met with the same peculiarity in many control slides, but I find certain differences between these in the ricin cases and those in the control. There is no increase in the numbers of the cells, but certain qualities in their bodies attract attention. They are universally much larger than in the

in the cerebrum were discovered, the alterations among the Purkinje-cell dendrites being most conspicuous. These are entirely robbed of their buds, the branches

FIG. 8.—Dendrons of the mid-portion of the second cellular layer, showing swellings and diminution of lateral buds. Ricin poisoning of 37 hours' duration. Subcutaneous inoculation of 1 mgm. ricin. Photo-micrographs by Dr. A. S. Hoen.

are irregular and gnarled, and the uppermost ones are entirely atrophied and have in part disappeared.

In conclusion, the study of the tissue changes in the cerebral cortex, which I have had the privilege of bringing before you this evening, show very absolute and positive lesions of the nerve cell induced by the action of a soluble poison in the limited space of a few hours and in a manner very similar to that in which we should imagine large quantities of a toxalbumin would act when it is engendered in the course of certain diseases of bacterial origin.

THE OPERATIVE TREATMENT OF INGUINAL HERNIA, WITH A REVIEW OF NINETY-SEVEN CASES — PREFERABLE METHOD OF OPERATION.

By J. COPLIN STINSON, M.D.,

SAN FRANCISCO, CALIFORNIA.

IN deciding on a cure of inguinal hernia the problem is to close the breach in the abdominal wall and furnish a canal for the safe transmission of the spermatic cord. Until the more recent methods, the results from operative treatment were failures in a large proportion of cases. Even now few are so successful that failures do not sometimes occur. I believe that in the immense majority of cases the operation is followed by a complete and permanent cure; that in the great proportion of those remaining the patients are greatly benefited by the operation; that even the slight disfavor with which the operation is regarded by some is due to the bad results obtained by surgeons whose technique has been imperfect. I would emphasize this point: that the operation¹ should not be performed except by surgeons familiar not only with the surgical principles involved but also with the special anatomical conditions associated with the hernia. In looking over my list of cases in which I performed or assisted in radical operations for herniæ while house surgeon at the New York Post-Graduate Medical School and Hospital and since I left that institution,

¹ Championnière.

FIG. 7.—Pyramidal cell from second layer of cortex in an advanced stage of degeneration. Acute ricin poisoning of 14 hours' duration. Intravenous inoculation of 1 mgm. ricin.

control, are swollen, even globular in outline. The extensions are also much thicker and more nodular than customary, though they do not cover more territory than ordinarily. Are these elements, which belong to the lymphatic apparatus, taking up the detritus from the degenerated nerve cells and becoming engorged?

In the cerebellum lesions equivalent to those found

I find they have numbered 97. An analysis of these, of the methods employed, of the results obtained, and the description and recommendation of what I consider the preferable method of operation may help to determine the question as to the value and justifiability of operative treatment. Of the 97 operative cases, 79 were inguinal, 5 femoral, 7 umbilical, and 6 ventral. Various methods were used in operating for inguinal hernia—Bassini's, Barker's, Macewen's, and a modification of Championnière's. As I stated at the beginning, an operation to be followed by a cure should fulfil the following conditions:

1. It should cause total obliteration of the hernial sac.
2. It should allow for safe transmission of the cord, *i.e.*, the cord should not be subject to pressure in any part of its course.
3. It should not result in atrophy or inflammation of the testicle, nor in pain, thickening, or inflammation, nor in any other manner interfere with the function of the cord and its structures.
4. The breach in the abdominal wall should be closed.

I shall now describe in detail what I consider the preferable operation for the cure of inguinal hernia.

1. The external incision begins nearly on a level with the anterior superior spine, is carried obliquely downward parallel with and about one-half an inch above Poupart's ligament, and ends at the centre of the external ring.
2. The incision divides the structures superficial to the aponeurosis of the external oblique; the latter is well exposed and a director passed through the external ring beneath this layer, which is slit up to about one-half an inch above the internal ring; the cut edges are lifted up and freed from structures beneath, exposing internally the internal oblique and transversalis muscles and sometimes the rectus, externally till the shelving sharp edge of Poupart's ligament is clearly seen.
3. The cord and sac are examined and any adhesions to surrounding structures separated. Next they are separated from each other well up within the internal ring. The sac is examined and carefully opened with a short snip of the scissors; the opening is enlarged with the fingers, and if any adhesions exist internally these are separated. If the content is omentum and is matted together, thickened, inflamed, or in any other manner changed, it should be tied off; each vessel in the omentum is to be ligated separately, and even the smallest oozing vessel must be tied. Hold up the sac, after removal of its contents, and where it merges into the general peritoneal cavity close it with a running suture of fine catgut. When released the sutured edge immediately slips back into the abdomen. The cord and its vessels are then examined and any varicose or superfluous veins¹ excised high up at the internal ring. Examine the canal² for masses of adipose tissue, which should be removed.
4. Expose the internal ring—an opening in the transversalis fascia—by retracting the internal oblique and transversalis muscles. Any masses of adipose tissue which crowd into the ring from the subserous tissue should be removed; take the cord and place it at the lower angle of the internal ring. Now close the internal ring with a tendon suture, commencing at the upper angle; suture from above downward, leaving only sufficient room at the lower angle for the cord and its full vessels to play through.
5. The edges of the aponeurosis of the external oblique are retracted and the edges of the internal oblique and transversalis (sometimes the edge of the rectus on the inner side) and the shelving edge of Poupart's ligament on the outer side are brought together with three or more interrupted buried tendon sutures; the cord is situated

beneath the above layers of sutured structures; at the lower angle close to the pubic bone only sufficient room is left for the cord and its full vessels to play through.

6. The divided edges of the aponeurosis of the internal oblique are brought together with a continuous suture.
7. The skin edges are brought together with a continuous catgut suture, without drainage.

The steps of the above operation are simple, easy to follow, and the operation may be quickly performed. In an uncomplicated case it can be completed, depending on the dexterity of the operator, in from fifteen to thirty minutes. It has many advantages and should be followed by better results than the other recent operations. It has all the advantages without any of the disadvantages of the Bassini operation. It will be observed that the cord is not disturbed, is not displaced, is not subject to pressure, is not transplanted between two layers of buried sutures, and is not on the stretch, as in Bassini's operation. The cord is not transplanted between the edges of the freshly cut muscular layers and thus subject to the liability of pressure from muscular contraction or from adhesions to surrounding structures from its internal to its external ring, as in Halsted's operation. In both the Bassini and Halsted operations the functions of the nerves and vessels of the cord and the cord proper may be interfered with by pressure on, abnormal position of, or adhesions to surrounding structures; and subsequent to these operations there may be thickening, swelling, tenderness, or inflammation of the cord, or atrophy, swelling, or inflammation of the testicle.¹ Thickening and swelling of the cord and its structures I have frequently seen follow Bassini's² operation. The natural position of the cord is at the lowest part of the internal ring, and in the operation I have described in detail its position has not been changed. As to the formation of a new internal ring this is absolutely unnecessary; the suturing of the enlarged internal ring reduces it to its normal size, nor is it necessary to place the cord superficial to the internal oblique and transversalis as in Bassini's, or superficial to the external oblique as in Halsted's operation, for reasons already mentioned and also for those following. After closing the internal ring as I have described, this orifice is small; the cord is not on the stretch but hugs its lower angle where it passes down into the pelvic cavity to the base of the bladder, whereas in the Halsted and Bassini operations the cord, from its new position and relations, is on the stretch and, entering the ring less obliquely, the ring with its contents is more like to favor a return of the hernia. The very high removal of the hernia sac,³ the removal of every altered portion of peritoneum at its neck, the separation of adhesions internally and externally with suturing of the neck of the sac with fine catgut, leave a smooth surface to the peritoneum, whereas if its neck were ligated there would be more or less puckering of the peritoneum which would interfere with the free movement of the bowels over its surface. In ligating the omentum it is necessary to remove those portions that are abnormal; altered omentum must not be returned to the abdomen, as it acts as a foreign body and has at times set up peritonitis.⁴ I would not advise the pulling down of healthy omentum and its removal, as trouble may follow. Several cases are recorded of local peritonitis. In one case the result was fatal

from internal hemorrhage, death occurring from slipping of the ligatures from the omental stumps. Even the smallest blood-vessels must be ligated before the stumps are returned to the abdomen, for the reason that there is a diminution of the muscular cells in their walls; consequently, if a small oozing vessel is returned, its walls do not contract and retract like those of other arteries, and an internal hemorrhage will result. Halsted lays great stress on excision of superfluous veins to reduce the size of the cord, and reports three cases of atrophy of the testicle following his operation. It is advisable where there is a varicose condition of the veins to excise them high up within the internal ring, otherwise no immediate and little or no remote benefit will be derived. It is obvious that if the excision is performed in the inguinal canal the bulk of the cord is not materially reduced at the internal ring. I have frequently met with slightly enlarged veins due to pressure of the sac and its contents; after removal of the sac the veins resume their normal size. It is highly important to remove all particles of fat from the inguinal canal, internal ring, and subperitoneal tissue, especially if the masses from the latter bulge into the ring. The closure of the internal ring is the most important step of the operation; most of the success depends on suture of this opening in the transversalis fascia. In closing the ring lift up its edges with forceps, thus avoiding injury to the surrounding and subjacent structures, especially the epigastric artery which runs along the inner side of the ring, and keep the immediate work well in view in the centre of the field of operation; suture the ring from above downward, commencing at the upper and leaving only enough room at the lower angle for the cord and its full vessels to play through. In the above step and for suturing the internal oblique and transversalis to Poupart's ligament a blunt-pointed hernia needle is to be preferred for passing the sutures. The cord and its structures are located beneath the sutured edges of above-mentioned structures. The character of the suture material employed is very important. Kangaroo tendon is the most suitable material for a buried suture. Great credit is due Dr. Marcy, of Boston, for bringing to notice the merits of this suture material. Tendon is the most suitable, it is non-irritating, and it is not absorbed for two or three months. Busse¹ in his experiments showed that perfect tendinous union does not occur under ten weeks, or just about the period for the absorption of kangaroo tendon.

I shall now proceed to analyze my cases. Kangaroo tendon was used as a buried suture in 82 cases, chromicized catgut in 5, silk in 5, silkworm gut in 4, silver wire in 1. In the cases in which tendon was used all the wounds healed by primary union except 2. In these the suppuration was slight and located superficial to the aponeurosis of the external oblique. In those in which catgut was used all healed by primary union, but in one case three weeks after the operation two sinuses formed; one closed, but at the last report the other was still discharging slightly. In those in which silk was used one was followed by suppuration with a subsequent discharging sinus. In those in which silkworm gut was used two of the wounds supplicated and cicatrization was not complete for weeks. During the healing some of the worm gut was thrown off. In the case in which silver wire was used catgut was employed to ligate the blood-vessels; this wound supplicated very badly and took weeks for complete cicatrization.

Final results.—Most of the operations analyzed were performed during 1893 and 1894, so that in many sufficient time has elapsed to enable us to judge of the results. In the 82 cases in which tendon was used there

has not been a single relapse, nor has there been any in the cases in which chromicized catgut was used. In those in which silk was used there have been no relapses, but in the one case in which a sinus formed the discharge continues and this will keep up, I think, until the silk is thrown off or removed by a second operation. In those cases in which worm gut was used there were no recurrences, but in the two cases in which suppuration occurred the resulting scars were not strong and as soon as cicatrization was complete, light, well-fitting trusses were at once supplied. In the case in which silver wire was used there was no recurrence. The resulting scar was not strong and here, too, a light-fitting truss was at once supplied as soon as cicatrization was complete.

Mortality.—In the 97 cases operated upon the mortality was *nil*. There was one case not included in my list, a neglected strangulated inguinal hernia. The patient was admitted to the Post-Graduate Hospital and was at once taken to the operating-room. Anæsthesia with ether was commenced, but he had not taken five breaths before respiration ceased.

I shall now refer briefly to the results obtained by Dr. William B. Coley, who operates at the New York Post-Graduate Hospital. Dr. Coley reports¹ 133 cases of operations for various kinds of hernia; 124 were for inguinal hernia. In 117 cases kangaroo tendon was used as a buried suture. All but 3 were traced. There were no relapses. The only case Dr. Coley reports in which recurrence took place after use of the tendon was one of umbilical hernia. In 2 cases silk was used. Both relapsed inside of three months. Chromicized catgut was used in 5 cases with no relapses. Dr. Coley's mortality was one death from pneumonia in a child, who died on the fifth day after operation. There was no abdominal complication nor suppuration in wound. Dr. W. B. De Garmo,² in a paper on the surgical treatment of hernia, strongly advocates the use of tendon as a buried suture.

Dressings and after-treatment.—In many cases aristol was dusted on the wound. Over this bichloride gauze was held in place by strips of rubber plaster; finally cotton and a spica bandage were applied. The scrotum was left exposed and the testicles were supported. Unless there were indications for interference, the dressings were not disturbed till the eighth day. By this time the catgut was usually absorbed. Firm dressings were reapplied and the patients were kept in bed two weeks, or longer if possible. If the bandages became loose they were reapplied and were not removed till one month after the operation. None of the patients wore trusses after the operations except those whose wounds supplicated badly and who had commencing relapse. The operation I have described in detail is to my mind the ideal one, has all the advantages with none of the disadvantages of the other recent operations, and I think has the additional advantages which I have endeavored to sum up in my paper.

219 GEARY STREET.

The Pyramid Limp.—We are given to understand that "the pyramid limp" is that state of body which falls upon one for two or three days after making the ascent of the pyramids. One is so much pulled and pushed at the time that little or no inconvenience is felt. There is no sign of soreness of joint or muscle until after one has slept, and then the trouble begins to brew; the second day of that man or woman is worse than the first; the climax is reached at the end of the second or beginning of the third day, and from that time the patient recovers slowly.

THE SURGICAL TREATMENT OF GALL-BLADDER DISEASE ILLUSTRATED BY THREE CASES.¹

BY HOWARD LILIENTHAL, M.D.,

ASSISTANT SURGEON TO MOUNT SINAI HOSPITAL.

THE title of this paper is, I fear, a little misleading. It is not my intention to bore you with an exhaustive *résumé* of the subject of gall-bladder surgery, but simply to take three cases which have lately come under my personal observation and see what lessons their histories may teach.

CASE I.—S. L.—, sixty-five years old, first came to me in May, 1893, complaining of frequent and very painful micturition. For some years there had been more or less trouble in urination, but the present exacerbation was caused by improper instrumentation. The man had a large prostate and I passed a soft instrument, intending to irrigate the bladder and deep urethra, when I felt the grating sensation of stone. The diagnosis was confirmed with a metal searcher. June 1st under chloroform I did suprapubic cystotomy, removing the three symmetrical stones which are herewith presented. There was cystitis and decided enlargement of the prostate, which delayed the closure of the wound during many weeks. All this time the patient was under daily observation in the hospital. The fistula eventually closed and the patient went home. He was taught to catheterize himself to get rid of the residual urine. I did not at that time know of the wonders which could be accomplished in such cases by double castration. On May 6, 1894, just about a year after I first treated the man, I was called to Brooklyn by his family physician, Dr. A. G. Meyersberg, to see him in consultation. The patient was suffering intensely because of spasm in urination. The urine contained pus and considerable mucus and albumin. There was frequent vomiting. Pressure over the kidneys failed to elicit great tenderness, but pressure to the right side of the epigastrium was intensely painful. The lower edge of the liver was well below the border of the ribs. There was no jaundice and there never had been. There was absolutely no previous history of gall-stone colic, but the present attack of illness had commenced four days previously with sudden and severe pain in the region of the gall bladder. The bowels had moved freely. There had been chills and when I saw the man his temperature was 105° F. Because of the vomiting and the location of the tenderness I diagnosed impacted gall stone and sent the patient to Mount Sinai Hospital, where he entered my service. The amount of urine passed made uræmia improbable. There was a marked remission of symptoms when I saw him again, which was in the evening of the same day at about nine o'clock, after a rough, jolting drive to the hospital, and I thought that possibly the stone had become dislodged. The gentlemen of the house staff diagnosed surgical kidney, but none of them would agree to the possibility of gall stone, though there was still some tenderness in the right part of the epigastrium. Until May 9th or for nearly three days the man was treated with diuretics and stimulants. Then his condition became so bad that I decided to explore the gall bladder at any rate, rather than let my patient die without making an attempt to help him by operation.

Under chloroform an incision of about four inches was made through the right rectus muscle and parallel with its fibres. On putting in my fingers I could not feel the gall bladder at all. It seemed to be entirely absent. I felt, however, a hard body under the liver and far back, which I at first took to be a nodule of

new growth. In the region of the gall bladder there was a cord of omental adhesions about as big as one's thumb. This cord was so well organized that I cut through it very carefully and only between ligatures. At last I entered a cavity containing about a drachm of pale mucus. The entire cavity was no larger than one's index finger and it seemed at first to end in a blind pocket. I assumed it to be the atrophied gall bladder. By means of a probe I found that there was a narrow channel with another cavity beyond this one and that it contained the hard mass I felt posteriorly. The impact of the probe showed it to be a stone of a very hard variety. It was firmly wedged in a little cavity it had made for itself and it was with the greatest difficulty extracted with flat forceps. There were no other stones present, but there was slight mural incrustation. The specimen I removed I present this evening. In its recent state it weighed five hundred and one grains. The specimen is a perfect prolate spheroid and is a very beautiful example of solitary biliary calculus. My operation lasted two hours and the man stood it well, but died of urinary suppression thirty-six hours later. Post-mortem through the wound showed double pus kidney.

This case presents a few points of interest. Whether or not there can be such a thing as a general tendency to stone formation in the viscera I should be interested to know. The histories of stone formation in urinary tract and in gall bladder are, of course, totally different. The second point of interest is the fact that the diagnosis was made without any previous history of gall-bladder or liver trouble and mainly because of the vomiting and local pain. Dr. M. H. Richardson, of Boston, who has written very interestingly on this subject (*Boston Medical and Surgical Journal*, April 28, 1892), has made a point of this very fact, viz., that in cases of impacted stone we may have to rely mainly on the subjective symptoms of the patient. There may even be no enlargement of the gall bladder or it may, as in this case, be atrophied so as to make palpation impossible. In one case in which Dr. Richardson waited for symptoms to develop which should clearly indicate need of operation there was ulceration around the stone, with peritonitis and death in a few hours.

Another point of interest is the lesson we may learn not to ascribe all of a patient's symptoms to some disease which you may have recognized in him, but to bear in mind the possibility of two entirely different diseases occurring simultaneously. I recognized the evident fact that my patient suffered from surgical kidney by infection from his catheter, but was not satisfied that all his symptoms were due to that trouble.

CASE II.—My second case was F. W.—, a married woman thirty years old, who was admitted to Mount Sinai Hospital on July 24, 1894. She had suffered for about two years with occasional sharp colicky attacks of pain, accompanied by nausea. The pain lasted for a variable time, from a few hours to several days. During the attack she was often nauseated and sometimes vomited. She had never been jaundiced. The history as she gave it was quite typical of gall stones. She was treated on the medical side of the hospital by Dr. Brill with olive oil and other cholagogues, but on July 28th she was turned over to the surgical service for operation, for which the patient herself earnestly begged. She was chloroformed and a three-inch cut was made over the distended and easily palpable gall bladder. On direct manipulation this viscus suddenly collapsed and it was with difficulty sewn to the skin and peritoneum, to be opened in the future. On the third day I tried to open the gall bladder, but it was still so collapsed that, fearing accidental entrance into the peritoneal cavity, I de-

¹ Read before the Medico-Surgical Society of New York, June 3, 1895.

sisted. On August 4th, however, the woman had an attack of gall colic with tense filling of the gall bladder, which was then easily opened and drained by tube. Forty-four stones, some of which are to-night presented, were removed. Now, in spite of this free opening and the fact that I could find no impacted stone, the patient had occasional attacks of colic. On September 8th I again operated for the purpose of exploring the cystic duct. Under chloroform a three-inch median incision was made and exploration with the hand was attempted. Nothing was found, so a large aluminium probe was inserted into the fistula remaining from the first operation for purposes of combined probe and digital examination. The sinus had been previously distended by a tupelo tent. What was my surprise and horror when I found the probe, which had passed through the dirty gall sinus in the free abdominal cavity; the gall bladder, even after a month's anchoring to the parietal peritoneum, having retracted. I at once sewed up the patient's abdomen, draining the track of the probe with iodoform gauze. For many days the patient was between life and death with local peritonitis due to gall infection, but finally she recovered and was discharged cured, not only of her gall stones and peritonitis but of her gall colic as well. She is at this writing pregnant with her sixth child, and is well. There is no hernia. She was discharged from the hospital on October 21, 1894.

This case is an almost typical one of gall stones, the interesting points being, first, that the symptoms were so severe with such small stones, while in Case I., with such an enormous stone, there were hardly any symptoms; and second, that the patient made a perfect recovery in spite of the entrance of a great deal of bile into the peritoneal cavity. Bile peritonitis is often fatal, although of slow progress. The case shows well the immense value of gauze drainage in abdominal wounds.

CASE III.—This patient was a man, Frank W., fifty-nine years old, who was on the medical side of the hospital under treatment by Dr. Rudisch. He entered the institution on the 22d of April, 1894, with a bad bronchitis, some jaundice, and a history of severe pain with loss of weight extending over two or three years. The pain was in the epigastrium, but it extended over to the left side, where there was a point of tenderness in the neighborhood of the spleen which had existed for but a few weeks. The man was emaciated and gradually became intensely jaundiced. His gall bladder was plainly tense and fluctuating. Palpation of the viscus was painful. Finally this gall bladder became so distended that the patient begged for relief, and after transfer to the surgical service I operated for exploration under chloroform on April 30, 1894, by a three-inch incision downward from the border of the ribs. I came upon the tense gall bladder, but, following it up with my finger, I felt no stone or tumor. I stitched the bladder to the peritoneum and on May 4th incised it. About ten ounces of bile-stained mucus was evacuated and exploration by probe revealed nothing. The man was temporarily relieved, but died May 18th of œdema of the lungs. The autopsy showed cancer of the pancreas with metastasis in the lungs and a nodule occluding the common bile duct.

This case shows the important fact that jaundice and a swollen gall bladder may exist without true liver or gall-bladder disease, and emphasizes the necessity for a guarded diagnosis even in cases which may look plain at first sight. I took this case to be one of impacted gall stone, and I do not see how, without having watched it from its inception, a differential diagnosis could be made. The operation was of course indicated to relieve the symptoms of tension from the distended gall bladder.

These three cases are as typically different as they

can well be and yet they can hardly be called rare. They illustrate quite aptly the usual forms of treatment employed in this rapidly developing branch of surgery.

A CASE OF POISONING FROM THE EXTERNAL USE OF ACETANILID.

By RICHARD C. NEWTON, M.D.,

ONE OF THE VISITING STAFF TO THE MOUNTAINSIDE HOSPITAL, MONTCLAIR, N. J.

THE following case has occurred in the present service of Dr. Love and the writer in the Mountainside Hospital, Montclair, N. J.

M. L.—, aged four, female, a healthy child, under treatment for extensive burns of right arm, face, and leg. Has been in the hospital for some time, and is receiving no internal medication. The burns of the face and leg have healed. The arm, however, still presents a large granulating surface. This is gradually cicatrizing and considerable quantities of pus are constantly secreted. The edges of this ulcer have been stimulated with balsam of copaiba, while acetanilid has been sprinkled over the central portions and a piece of lint smeared with boracic acid has been put over all.

This plan of dressing the ulcerated surface has been used in all five times, covering a period of nine days, the arm as a rule having been dressed every other day. The amount of acetanilid made use of ranged between twenty and forty grains. It happened, however, that the arm had been dressed on Saturday, January 25, 1896, and again on Sunday, January 26th. On the latter date the dressings were applied at about twelve o'clock noon, and in about four hours the child complained of pain in her bowels and seemed faint and sick. She passed into a state bordering upon collapse. Pulse, 160; rather weak. Temperature not taken. Respiration, 22; not stertorous nor sighing. Eyes glazed and staring, with widely dilated pupils. Facies extremely cyanotic. Extremities cold. Patient lay perfectly motionless upon her back. No involuntary evacuation of urine or fæces. No diaphoresis observed. In about three hours after the first appearance of the cyanosis the patient vomited three times a thin greenish material. The vomita ran out of the mouth without apparent effort on the child's part.

As she was known to be constipated she received an enema of warm water, about a pint and a half. Some improvement in the symptoms was immediately noted. A fairly copious although constipated movement from the bowels was obtained.

As the materials that had been used in dressing the burn were not thought of at the time, the real cause of the distressing symptoms was overlooked and the condition was attributed to the constipated state of the bowels and the fact that the little girl had surreptitiously partaken of some rich cake.

After the vomiting above alluded to and the movement of the bowels the child fell asleep. She was still somewhat cyanotic and did not become warm to the touch until hot bottles had been put into the bed. The next morning she was as well as usual.

On Tuesday, January 28th, the same method of dressing the burn was pursued, and no evil consequences are known to have followed.

On Thursday, January 30th, the arm was dressed again in a similar manner. In about an hour after the dressing the child complained of pericardial distress and was pale and weak. These symptoms passed off for an hour and a half and then recurred. The appearance, decubitus, and pupillary symptoms were similar to those of the former attack. At 4 P.M.

the pulse was 140. Temperature, 97½ F. Respiration not recorded. In this attack there was no emesis; and on the whole the symptoms seemed less severe than in the attack four days previous. A drachm of whiskey in hot water was given per os and was followed by some amelioration of the symptoms.

At 5 P.M. my colleague, Dr. Love, saw the patient and was at first inclined to believe her in extremis. He ordered her ten drops of aromatic spirits of ammonia every half-hour until the condition improved, and then every two hours.

I saw her myself at 8:30 P.M., and even then her appearance was calculated to excite alarm. Dr. T. Y. Sutphen, of Newark, was with me. The most striking feature of the case was the utterly helpless and impassive condition in which the little creature lay. The cyanosis, the widely dilated fixed pupils, which responded very slowly if at all to light, and the cold and clammy skin, made a strong impression on my mind, occurring as they did in a child that I had seen actively moving about and crying and fretting about her arm being dressed a few hours before.

She received one-sixtieth of a grain of strychnine sulphate in addition to the treatment already detailed, and was as before all right again in the morning.

I might say in passing that three attempts have been made to graft skin upon the extensive ulcer of the right arm (the face and leg burns having already cicatrized over). The first was by Thiersch's method, and was partly successful. The last two were done with skin taken from two blisters on the arm of a healthy man and failed utterly.

Comment upon the above case seems scarcely necessary. There can be no reasonable doubt that it was a case of acetanilid poisoning. On the second occasion there had been no indiscretion in diet and nothing of an indigestible nature was in the stomach. It will be observed that the first instance of poisoning followed the second application of acetanilid within a period of about twenty-four hours and the second instance followed the last of five applications, which would seem to indicate that instead of the system becoming immunized to the drug it tends to grow more susceptible to its influence. Perhaps for some reason which we cannot explain the drug was more readily absorbed on the two occasions when it did harm than on the three occasions when it did not seem to have any evil effect. The nurse who dressed the arm on January 30th is sure that less of the drug was sprinkled on the ulcer than had been used on former occasions.

After this pointed warning we must certainly be more circumspect in the use of acetanilid as a surgical dressing than the writings of a number of surgeons would lead us to suppose necessary. It has been used a number of times as a dressing in the Mountain-side Hospital, but hereafter its use will, I presume, be suspended.

Frollington and Pratt, at the conclusion of a carefully written paper in the *American Journal of the Medical Sciences* for August, 1895, p. 156, announce that "there is no danger of poisoning from absorption of acetanilid." Dr. Bradinox, of Louisiana, and Dr. T. S. K. Morton, of Philadelphia,¹ report extensive use of this drug, the latter having "just published his observations in one thousand surgical cases with marked success." Without attempting to go into the literature of acetanilid as a dressing, the above quotations will show that it has been recommended on high authority. From the number of times that it has been spoken of in current medical literature its use must be on the increase, and a word of warning against its indiscriminate use cannot be out of place.

¹ Squibb's Ephemeris, January, 1896.

I have seen somewhere recently, although I have mislaid the reference, an account of a case in which serious symptoms of intoxication followed the use of acetanilid as a dusting powder upon the navel of a newly born infant. Strychnine was used as the remedy in small, frequently repeated hypodermic injections, and the patient recovered.

This case and my own only show that in using the coal-tar products externally we are not freed from the dangers which attend their internal exhibition; that they are remedies whose powers, limitations, and dangers are not yet understood; and that many statements made in regard to them have proved misleading in practice.

And, lastly, there is no doubt that many more carefully conducted experiments are needed, and especially a very large number of accurately recorded clinical observations must be furnished, before the true place in medicine of these peculiar agents can be determined.

MONTCLAIR, N. J., February 11, 1896.

TECHNIQUE OF MASSAGE OF THE STOMACH.

By GUSTAF NORSTRÖM, M.D.,

NEW YORK.

ONE knows, and I have already said in my "Traité du Massage," that, if massage yields good results in some cases of nervous gastralgia, it is on the contrary often insufficient or even useless in chronic gastritis and in affections presenting a real alteration of the walls of the organ.

This want of success is easily explained if we consider on one side the deep situation of the stomach and on the other the slight resistance of the deep plane on which it rests.

On account of these different causes one is able to mass only a very limited portion of the anterior wall of the stomach, the rest withdrawing under the pressure or not being reached because of its distance from the abdominal wall.

However, in a certain number of cases I have obtained amelioration or even definite cure, but in almost all of these the thinness of the abdominal wall and of the skin and the flattening of the thoracic cage allowed me to seize the diseased organ without too much difficulty—physical conditions which are very rarely realized.

I have wondered if it would not be possible to place the patient in such a position that the stomach might become, as does the intestine in the genu-pectoral position, easily accessible to the hand.

The massage of the stomach is ordinarily performed with the patient in the dorsal decubitus. About three years ago, finding myself in the presence of an invalid with a very thick abdominal wall, it occurred to me, in order more easily to seize the organ, to make him lie on the right side, the left going beyond the vertical plane.

I was then astonished at the facility with which I could seize and mass the stomach. In cases of gastric dilatation I obtained the sound by means of very small succussions, and, in a word, the organ *entraîné* by its own weight fell, if I may say so, into my hand ready to undergo the different manipulations that I wished to perform.

To this way of operating the following objection has been made: The object of massage being to make the aliments circulate from the cardia to the pylorus, is not the contrary effect obtained through massing from the pylorus to the cardia? To this I answer that the object of massage is not only to make the ali-

ments circulate in the stomach, but also and above all to restore the tone of the muscular fibres of the organ, and, these fibres being circular, the direction of the pressure is a matter of little importance. As to the aliments, we begin by driving them from the cardia to the pylorus by massing the patient in the dorsal decubitus, then we make him lie on the side, and finally we end by a new massage in the dorsal decubitus.

The following is the exact *modus faciendi*. The patient is placed in the dorsal decubitus with the legs bent and the head somewhat raised. The breathing ought to be free and the meal to have been taken a few hours before. One has indeed wondered whether massage performed during the digestion did not delay this physiological act, but the experiences of Gopadze and especially those of Dr. Beulet,¹ of Berne, have on the contrary proved that the acceleration imparted by massage to the peristaltic movements and the increase in the production of the gastric juice through the excitation of the glands stimulates the gastric function. The duration of the digestion can thus be diminished by more than an hour. The aliments remain then for a shorter time in the stomach, they are better assimilated, and the best proof that we may give thereof is the diminution of the quantity of fæces, a diminution that is great enough to frighten some patients.²

Another advantage of performing massage two or three hours after the meal is the avoidance of the rippling noise which is so unpleasant to the patient and which is almost always produced, especially if there is the slightest dilatation of the organ.

These conditions fulfilled and the patient being placed in the dorsal decubitus, massage is at first performed from the cardia toward the pylorus for a few minutes, as in the old method; then the position is altered, the patient lying on the right side, and petrissage is performed on the stomach with both hands, alternately, from the pylorus toward the cardia, dwelling for some time on each of the regions of the organ as one does for the colon in cases of constipation.

Generally, after a few sittings the patient gets accustomed to the treatment and one is able to mass easily. In very unfavorable cases, that is, when the organ is very sensitive or the patient very pusillanimous, one is obliged to use great gentleness during the first five or six *séances* in order to let the unpleasant confusional sensation pass away before beginning the definitive petrissage.

The amelioration most often shows itself by the return of the appetite, then follows very rapidly the disappearance of the spontaneous rippling, the eructations, the gastric pains, the cephalalgia, the vertigo, etc., in a word, all the symptoms of gastric affections.

The sittings ought to last about a quarter of an hour when one has to treat the stomach exclusively, but most often the different diseases of this organ are attended with constipation and it is necessary to mass the intestine at the same time.

What is exactly the action of massage?

It is a double one. Massage acts at the same time on the muscular tunic and on the secretion of the glands of the organ.

It acts on the muscular fibres of the stomach to make their atony disappear, the same as it acts on the muscles of atrophied and paralyzed limbs.

Its action on the glands is equally obvious. The recent experiences of Dr. Colombo, of Turin, although they relate to animals only, show perfectly well that massage stimulates the glandular secretion

of the stomach. Dr. Colombo made gastric fistulæ in dogs on which massage had been performed and noted a marked increase of secretion.

He concludes from these experiences that massage acts on the glands through a double process: on one side it stimulates the working of the glandular epithelium; on the other it determines in the organ a more abundant afflux of blood, which favors the filtration.

Besides this special action on the gland itself, the secretion of the gastric juice is also increased through the acceleration imparted to the peristaltic movements by the first and last period of massage. This action is immediate and one not rarely sees dyspeptic persons become relieved immediately after the first treatment by massage. They say that they feel lighter, their "food is no longer on the stomach." Nevertheless, as much as possible one must prevent the patient taking too large a quantity of aliment at the beginning of the treatment. During the first days he must submit to a diet, and little by little one brings him back to his habitual regimen, suppressing, however, any indigestible aliments he may have been using. This return to the habitual regimen is only made according to the indications given by the state of the patient, and it is more or less rapid according to each case.

I have spoken in my "*Traité du Massage*" of constipation in neuropaths. The indications are the same in gastric affections of nervous origin, of which gastralgia without material lesion is the principal type. Massage in these cases often gives excellent results, especially if one associates with it the general treatment appropriate to their state, a treatment which we need not describe here.

We must also notice the results which one obtains in dilatation of the stomach. I do not believe that this disease is as frequent as it is generally said to be. Bouchard, who has given an excellent description of it, says that writers have too often called by the name of "dilatation" affections which were nothing but simple gastralgia or chronic gastritis, and in this view we may see dilatation everywhere. On the contrary, we shall find that the number is much more limited, if, besides surgical cases, which we have not to occupy ourselves with here (polypus, cancer, etc.), we consider only that idiopathic form of dilatation which is produced under influence of a nervous trouble.

In this kind of dilatation one almost always obtains excellent results through massage, and by excellent results I mean the diminution or the disappearance of the morbid symptoms, without the volume of the stomach being diminished in any obvious way.

I have noticed in these cases frequent relapses. It is not so in the dilatation of the stomach consecutive to a chronic gastritis in which the production of flatus in large quantity results in a mechanical distention of the walls, a distention which massage soon removes. The gastritis which is the cause thereof disappears at the same time and the results are most favorable.

Only one thing is to be regretted and that is that this affection is not sooner submitted to our treatment. We are consulted only when the muscular tunic has undergone considerable alteration because of the prolonged distention of its fibres. Besides, this great dilatation explains the necessity of submitting the patient to a relative diet, so that the wall of the stomach may become more supple and consequently more easy to reach. In the contrary case the hand slides, as it would on a bladder filled with water or air.

In dyspepsia, which by some authors is ranged in a particular class but which I regard as due only to chronic gastritis, massage renders great service, and it is not rare to see the patients relieved after only a few sittings.

¹ Beulet, Correspondenzblatt für Schweizer Aerzte, March, 1888.

² Last year an elderly lady got so frightened at the diminution of her stools that she asked me if a part of her fæcal matters did not hide itself somewhere in her belly.

Gastralgia may be ranged in two classes: essential gastralgia and that which is dependent upon a diathesis (anæmia, neurasthenia, etc.). These last although they derive good effects from massage, are completely cured only when one has at the same time through appropriate means made the cause which has produced them disappear. As to essential gastralgia, I have rarely seen it resist a massotherapeutic treatment, and, strange to say, what one often meets with in neuralgia of other parts of the body, it is frequently after the second or third sitting that the patient begins to feel relief.

I might cite among others the case of a young lady who had suffered for a certain number of years from violent gastralgia, and who was cured after relatively few sittings of massage. I saw her two years later. She had not noticed any return of the symptoms of her disease.

Finally, in cramp of the pylorus, which is an affection rather difficult to diagnose and, besides, not frequent, I have also performed massage with entire success. The cramp of the pylorus most often attends chronic gastritis. It is a painful affection, which is frequently produced at regular hours, principally during the night, and which ceases only when the contracture of the muscle has at last yielded and left passage for the flatus accumulated in the stomach. The cramp of the pylorus is often confounded with other gastralgia; it is especially important to make its differential diagnosis from the pyloric crisis that attends the ulcers or tumors of this orifice, because in the latter massage may be dangerous.

Clinical Department.

HÆMOPHILIA: AN UNRECOGNIZED CASE WHICH TERMINATED FATALLY AFTER EXCISION OF THE KNEE-JOINT.

By J. E. SUMMERS, JR., M.D.,

OMAHA, NEB.,

PROFESSOR PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY,
OMAHA MEDICAL COLLEGE.

HÆMOPHILIA is described as a disease, nearly always hereditary, characterized by a predisposition to bleed either spontaneously or as the result of the mildest of traumatisms, the hemorrhage being usually parenchymatous. The predisposition may be transmitted through many generations, but "bleeders" are chiefly limited to males, the transmission, however, being handed down almost always through a female, who herself is usually free from the diathesis. It is estimated that hæmophilia is observed relatively in males and females, in the proportion of twelve to one. According to Treves,¹ hæmophilia has a peculiar geographical distribution, being common in Germany and in Great Britain, North America, Norway, Sweden, and France, but is not observed in Spain, Portugal, Italy, Turkey, or Greece. Hæmophilia is more common among the Jews than any other race.

No pathological lesions have ever been demonstrated in a sufficient number of cases to raise the etiology of hæmophilia from among the "unknown," for as yet, in nearly all cases, both the blood-vessel walls and blood have proven to be normal, as far as the means employed have enabled the pathologists and chemists to determine (Tillman). However, it cannot but be true that either there must be some lack of tone in and construction of the vessel walls, or the power of coagulation of the blood is abnormal. That the latter may be a causative element is proven by the predisposition to hemorrhage in patients, the sub-

jects of leukæmia, in whom dangerous, even fatal, hemorrhages may follow otherwise trifling traumatisms. As an illustration: very recently, and since the fatal case which prompts this paper, I was consulted regarding the removal of an enlarged spleen from a man, a victim of pronounced leukæmia. I declined the honor of the operation and counselled strongly against allowing any one else to perform it, more especially as an alarming hemorrhage had, only a short time previously, followed the extraction of several teeth. Strangely enough, no bacteriologist has as yet claimed to be the discoverer of a causative germ in hæmophilia. Nancrede² says: "Histological examination of the vessel wall has only once afforded confirmation of the statement of Blagden, made in 1817, that the walls are unusually thin, Kidd finding degeneration of the muscular tissue of the middle coat of the arteries and proliferation of the endothelium of the arterioles, veins, and capillaries." Besides hemorrhages occurring either traumatically or spontaneously from or beneath any subcutaneous or mucous surface, blood may be poured out around or into joints, and, as a result, produce changes in the joints which may resemble strongly diseases having other etiological beginnings—such, for example, as tuberculosis and arthritis deformans. According to Bowlby,³ this hemorrhage into the joints is sometimes followed by an arthritis not to be accounted for simply as a result of the hemorrhage; the arthritis resulting occasionally in loss of function and deformity, with either fibrous or bony ankylosis.

From birth to the age of puberty is the period when hæmophiliacs are most prone to bleed, especially at the latter, and at the time of dentition and the appearing of the permanent teeth.

Late in August of this year, a boy, ten years of age, was brought to me by Dr. Lukens, of Herman, Neb., with the request that I do something to straighten an ankylosed, crooked knee. The boy's parents were Germans of the lower order and apparently healthy. There was a family history of tuberculosis. The boy himself was very stupid. The history given was that, about two years before, there had been pain, inflammation, and some swelling in the knee, the limb gradually assuming the flexed position, until at the time the case was brought the leg was flexed upon the thigh at an angle of one hundred and thirty degrees. At this time there was very little swelling, and the characteristic position so often seen in the knee-joint tuberculosis was present. I judged it to be a cured or quiescent tubercular arthritis, of which I had treated many. The boy was put to bed, and a weight and pulley applied, the intention being to use the Thomas knee-splint. About one week later a more careful examination than circumstances rendered possible on the day of admission into hospital satisfied me that the ankylosis was bony, and not fibrous as I had first supposed, and the limb was ordered prepared for a resection on the following day. Just prior to the giving of the anæsthetic, being informed that there were several fading "black and blue" spots on the boy's arms and thighs, I made a careful inspection, and quizzing him elicited that the ecchymoses were the result of floggings received at home, thus relieving my mind of the doubt raised as to the propriety of any operative procedure in his case. The operation was done by a horseshoe incision, convexity downward, and was devoid of interest. The inflammation had resulted in erosion, in places, of the cartilages forming the joint, with union of the apposed eroded surfaces. The crucial ligaments were only slightly involved, and the capsule did not seem to have taken a prominent part in the pre-existing in-

¹ Dennis' "System of Surgery."

² Garrod in "Twentieth Century Practice of Medicine."

flammation. The patella, which was united to the femur, was removed. Catgut stitches and drains were introduced, and the usual dressings and a posterior splint completed the operation, the boy being put to bed in excellent condition.

On the afternoon of the day of the operation, pain being complained of, the bandages were slightly loosened. Early in the evening the nurse, noticing that there was a little bloody discoloration of the dressings, and a short time later that this was rapidly increasing, the boy showing the usual symptoms of hemorrhage, a tight bandage was put on and I was summoned. Immediately after my arrival I applied a rubber bandage from the toes to the groin, expecting this to control the bleeding, as I felt confidence in my technique, and that no injury could have possibly occurred to the popliteal vessels, the other vessels necessarily divided having been carefully attended to; besides, none of them is of sufficient size to ever cause any serious post-operative trouble.

The limb was well elevated, likewise the foot of the bed, and some paregoric was given. Being informed in about two hours that there was oozing still going on, I summoned a colleague, realizing the possible nature of the case. Ligation of the common femoral and reopening of the wound for the discovery of the source of bleeding were discussed, but it was decided to apply another rubber bandage over the first, hoping in this way to control the hemorrhage. The symptoms of loss of blood were marked; paregoric and ergot were given internally, and a hot saline solution per rectum. The oozing, though slight, was progressive during the night, and next morning, under ether. I removed the dressings and reopened the wound. A careful examination failed to disclose any bleeding vessel, and there was practically no hemorrhage from the raw surfaces. Packing iodoform gauze between the bony surfaces and into all parts of the wound, the limb was re-dressed and placed upon the posterior splint, with a rubber bandage lightly applied over all. Hemorrhage recurring, a hot saline solution, six per cent., was introduced into the circulation at the elbow. This being repeated in the afternoon, the other arm being used, nearly two quarts were introduced altogether. Strychnine and digitalis were given hypodermically, and rubber bandages were applied; but all was vain, the boy gradually sinking and dying during the night. Had any one told me that a patient of mine could die of hemorrhage from a wound of an extremity, with modern armamentarium at hand, and the patient in hospital, I would have smiled and thought: from a wound of the head or trunk, possibly; from an extremity, never.

This was a true case of hæmophilia, although nothing has been learned of the family history confirmatory of its heredity. The slight incision through the skin necessary to open the median cephalic vein gave much trouble, and in one arm the oozing continued until death. The use of the hypodermic needle was followed by subcutaneous hemorrhages as large as the palm of one's hand. König reports several experiences similar to my own. Unfortunately, the specimens removed at the operation were lost, but I am of the opinion that the joint lesion was one of hæmophilia in its late stage, which so resembled a common type of tuberculosis that it was mistaken for it. Should such an accident occur again in my practice, I believe I would reopen the wound immediately, and pack gauze impregnated with some preparation of iron or well dusted with antipyrin, and the ends of the bones might be puttied, if I may use the expression, with the resultant of the mixture of antipyrin and tannic acid, as recently recommended by Parke.¹ Further than this, I would repeat my efforts used in this case.

¹ Medical News.

It is unwise to state, as do some, that hæmophilia is not so dangerous a diathesis as to make surgical operations very dangerous; several cases of success may have been in mild forms of what is usually a most serious condition, only justifying surgical operations when they are lesser evils than the conditions suggesting them.

Probably something may be done as prophylactic measures against hemorrhage in hæmophiliacs in whom it is absolutely necessary to perform a surgical operation, especially if sufficient time is given to build up the general system and administer chloride of lime, camphor, and turpentine for the purpose of gaining their supposed effect upon the blood; the first rendering the blood more coagulable, the others increasing the number of the white corpuscles (Treves). This latter I regard as very poor theoretical therapeutics, for we know that an increase of the relative proportions of the number of white blood corpuscles to the red predisposes to hemorrhage. If they are of any practical value, it is brought about in some other way than by an increase of the number of white corpuscles. Finch's recommendation and successful experience in three cases of the use of venesection can hardly be recommended, especially as he employed hot-water irrigation as an adjuvant; venesection lowers the blood-pressure and thus aids coagulation, but he must be a bold man who would bleed a recognized bleeder. The hot water was the remedy which probably saved these three patients. The actual cautery is equally recommended and condemned. Intravenous injections of hot saline solutions is, I think, to be recommended. They certainly prolong life, and thus give time for aiding nature in every way possible. For the purpose of introducing a saline solution into the circulation, I use a nozzle of glass or hard rubber similar to that employed by undertakers in embalming. This nozzle has a shoulder on the tip near the point, against which the upper ligature rests, thus preventing slipping and leakage; it is cheap and should be made in several sizes, and can be attached to the tubing of any fountain syringe. The practical facts in the treatment of bleeding in hæmophiliacs are that bleeding from slight wounds, easily accessible for the application of treatment, can be successfully handled, even when the type of hæmophilia is severe. In extensive wounds, such as in my case, the result will probably be unfavorable. In mild types of the disease almost any of the numerous recommended methods of treatment will usually prove successful.

A TEST FOR ALBUMIN IN THE URINE.

BY DR. ALEX. C. EWING,

SALT LAKE CITY, UTAH.

I FEEL that I owe the readers of the MEDICAL RECORD an apology for even suggesting a test for albumin in the urine. It is, however, not a new test but a simple way of applying an old one. It is this: Draw up into a small glass pipette or tube about an inch of the urine, let the finger remain tightly over the top and insert the pipette into nitric acid and draw up under the urine about the same quantity of acid, when if even a trace of true albumin be present there will appear a beautiful line of demarcation between the acid and urine. This test is as accurate as it is simple and, besides, is decidedly economical and far less trouble than all others.

The Mortality Rate among Medical Men of France is 26 per 1,000, the actual number being about 450.

A CASE OF UNUSUALLY EARLY MENSTRUATION.

By E. G. WOODRUFF, M.D.,

ALBURN, N. Y.

I DESIRE to report the following case of menstruation in a child aged six years and two months, whom I was able to see and examine through the kindness of Prof.

A. Monti at the Polyclinic in Vienna on January 23d. As the reader will readily observe from the accompanying picture, the face and general appearance are those of a well-developed girl of fourteen or fifteen years of age. The child is of the brunette type, and stands 118 cm. in height.

The chest measure is 72 cm. and that of the pelvis with the pelvimeter is as follows: At the crest of the ilium 20 cm., at the anterior superior spine 21 cm., and at the great trochanter 25 cm. Upon inspection I found the breasts to be full, firm, and round.

The mons veneris was covered with hair. The hymen was present, and the uterus was found on rectal examination to be normal.

According to the statements of the mother, the child began to menstruate at the age of two years, and has done so regularly since, the flow being normal in amount.

Menstruation appeared as usual between the twelfth and fourteenth years in the mother and five sisters of the child. The general health of the child seems up to the present time to be undisturbed in any way by this menstrual precocity.

THREE CASES OF ENURESIS SUCCESSFULLY TREATED BY SIMILAR METHODS.

By A. RUSSELL STRACHAN, M.D.,

NEW YORK.

A GENTLEMAN called at my office to report the fact that his two children, one a boy of six years and the other a girl four years of age, were in the habit of passing their urine incontinently, "wetting their clothes and their beds," and requested me to make an appointment to see his family physician in consultation regarding them, as every means known to them had been tried ineffectually to correct the habit during the previous six months.

An examination of the lad showed that he had phimosis with the foreskin very adherent to the glans penis. As the foreskin was not unduly long I did not recommend circumcision, but simply stripped it back from the glans and stretched it with a dilator. The girl on examination I found to be in a similar condition as to her clitoris, the glans being scarcely observable and the mucous membrane surrounding

being firmly bound down over it by adhesions. These latter were carefully dissected back until the glans was entirely free. Simple antiseptic dressings were applied in each case and an absolute and immediate cure resulted.

The third case was that of a young lad, fifteen years of age, who was brought to me by his father, who had been obliged to remove him from an academy where he had been studying, owing to the fact that he "wet his bed" each night and had come into disfavor. He was a well-formed, bright-looking boy, but bashful and shamefaced in manner, owing to the nature of his trouble. His father stated that all manner of treatment had been adopted for the correction of the habit, severe corporal punishment included, but without any good result, and that latterly he had feared the effect upon his son's mind might drive him to the commission of some desperate act and so had brought him home to be as much as possible under his own personal supervision. Examination showed a very long and very adherent prepuce and I recommended circumcision, which was done at once, the adhesions being overcome with difficulty. But the operation was very successful and entirely and immediately cured his enuresis.

I report these three cases as being typical of an important class. My attention was first called to them by a Jewish doctor in Paris many years ago in discussing the rite of circumcision. The point made by him as affecting the female was new to me, but I have since often found it as important in many of these reflex disturbances as in that of the male subject, and I think it calls for more careful inspection on the part of the obstetrician as to the condition of the genital organs of the infant after birth before he considers his obligations fulfilled than is generally conceded, especially in view of the serious suffering neglect at that period may entail later in life.

Progress of Medical Science.

Uræmic Pericarditis.—Pericarditis is a frequent complication of chronic nephritis. From an editorial examination of the subject published in a recent issue of the *Journal of the American Medical Association*, we learn that Buhl estimated the frequency at thirty-five per cent. of the observed cases; Bamberger, at fourteen per cent., and Wagner observed pericarditis fourteen times in one hundred and fifty cases of chronic nephritis. Many of the earlier writers believed the cause of this inflammation of the pericardium as well as of other tissues in the course of chronic nephritis to be toxic substances circulating in the blood which the kidneys failed to eliminate. Under the influence of the study of bacteriology the opinion gained ground that pericarditis in connection with nephritis must be due to an accidental infection, and this was the view expressed by Lecorché and Talamon in their treatise on albuminuria and Bright's disease published in 1888. It is self-evident that in order to determine the exact cause of the pericarditis in a given case, resort must be had to the modern microscopic and bacteriologic examination of fresh material as soon after death as possible. There are already a few records published of the examination of such cases and especially by Banti, of Florence. He described a case of pericarditis in a uræmic in 1888 (*Deutsche med. Wochenschrift*, No. 44, 1888) in which the exudate and the tissue of the pericardium seemed absolutely free from bacteria as far as could be determined by microscopic examination, by culture experiments, and by inoculation into animals. Baumgarten (*Baumgarten's Jahresbericht*, Bd. iv.) was inclined to

think that the inflammation in this case was due to micro-organisms that had died before the material was examined, but Banti was not inclined to accept this criticism, because the pericarditis had existed only seven days before death. Last year (*Centralblatt für allg. Path. u. Path. Anat.*, Bd. v., No. 11) Banti described a new case of pericarditis in uræmia due to arteriosclerotic interstitial nephritis, in which the exudate and the tissue of the pericardium were found free from microbes after the most thorough examination according to the best methods. Aerobic and anaerobic culture experiments were made with large masses of the exudate upon a variety of media, but all remained sterile. In this case the clinical manifestations pointed to the existence of the pericarditis for about four days before death. Banti consequently concluded that in the light of the results obtained from the study of these two cases, the pericardial inflammation was due to toxic substances circulating in the blood in consequence of failure of elimination through the diseased kidneys. He then made some animal experiments and found that rabbits in which the pericardium had been cauterized developed a more marked fibrinous pericarditis after nephrectomy or ligation of the ureters than did animals in which the cauterization of the pericardium only was made and which were killed after the same length of time in which the uræmic animals died. While these experiments were not conclusive, yet they seem to support the theory of uræmic pericarditis. In October, 1894, Beco (*Centralblatt für allg. Path. u. path. Anat.*, Bd. v., No. 19) describes a germ-free case of sero-fibrinous pericarditis in a chronic nephritic, which he is inclined to interpret as due to toxic substances produced by the bacillus coli communis which was present in the blood and in the spleen. This view is supported by certain experiments of Charrin (*Sem. Médicale*, 1894, No. 42, p. 337), which seem to show that the bacterial toxins may cause serositis without the immediate presence of the corresponding micro-organisms. In March, 1895 (*Centralblatt für allg. Path. u. path. Anat.*, Bd. vi., No. 5), Banti describes two additional cases of uræmic pericarditis in which there were no bacteria either in the pericardium, in the blood, or in the spleen, and he concludes that the presence of the bacillus coli communis that Beco found in his case was accidental and due to agonal or post-mortem invasion. From these interesting observations it does not seem unreasonable to believe that there may be a "toxic inflammation" independent of all direct bacterial influence. Such observations as Banti's and others indicate the necessity of a thorough bacteriologic examination of all cases of pericarditis and other serositis in connection with kidney lesions in general. The results obtained are in full harmony with the views concerning auto-intoxication that are rapidly gaining credence at the present time.

Physical Signs in Diseases of the Stomach.—

Drs. Hayem and Léon, who have pointed out anew the peculiarities frequently met with in gastric affections, state that inspection alone is often of decided value in establishing a diagnosis. These French observers inform us that (1) Prominence of the abdomen in the upper part is seen in large eaters, such as diabetics. (2) Prominence below may occur in many conditions, as in women who have borne many children, gastrop-tosis, etc. (3) A central prominence extending from the lower part of the sternum to below the umbilicus is seen after a full meal in patients with pronounced dilatation without ptosis of the stomach. (4) Flattening of the abdomen with hypogastric prominence occurs in those having dilated stomachs with ptosis. A slight transverse ridge may often be seen corre-

sponding to the lesser curvature of the stomach. The abdomen observed in profile may show: (a) A sub-sternal hollow; this occurs in inanition, frequent vomiting, etc. (b) An abnormal prominence, mostly sub-sternal or epigastric, due to distention of the stomach. (c) A flattening of the epigastric region with hypogastric prominence seen in gastric dilatation with ptosis.

Curettage for Puerperal Fever.—Dr. Rapin, of Lausanne, employs curettage for puerperal fever. The debris remaining in the uterus after labor and constituting the greater part of the lochial discharge aids in the development of septic endometritis. This is proved by the fact that in cases that have been curetted the lochia ceases in two or three days. Anti-septic intrauterine injections should be used when the temperature rises to 38° C., with fetid discharge. If a marked change for the better is not observed in twenty-four hours proceed to curette. Out of 34 cases Dr. Rapin had 6 deaths, several of which were in desperate condition when they came into his hands. In 13 cases cure was effected in three days; in 7 in less than eight days; and in 8, in twelve or fifteen days. In 1 case in which chronic puerperal fever without localization had continued thirty-two days a cure was effected in twenty-four hours. These facts show that in puerperal fever the process of infection is carried on in the uterus and the symptoms are due to intoxication of the blood by toxalbuminoids and not to infection of the blood by microbes. The operation should be performed early. Any danger of rupture of the uterus, which is sometimes urged as an objection, may be avoided by proper precautions. This accident occasionally follows intrauterine injections.—*Gazette des Hôpitaux*, October 5, 1895.

Excision of the Gut in Tuberculosis of the Cæcum.—Primary tuberculosis of the cæcum is rare, but in the past ten years Dr. Durante, of Rome, has had five cases of this kind under his care. In a report of the proceedings of the Academia di Medicina of Rome, published in the *Deutsche Medizinische Zeitung*, January 6, 1896, we are told that Dr. Durante considers the diagnosis of cæcal tuberculosis by no means easy. According to his personal experience the early symptoms may seem to denote only chronic diarrhœa. This may last for months or even years. Then defecation will become increasingly difficult. Signs of obstruction next arise, and finally complete stenosis may develop. Cachexia, which in malignant neoplasms comes on early, may not appear until the tuberculosis is far advanced. In his own cases the tumors of the cæcum attained about the size of a lemon. The appendix may or may not be involved. In one case the Italian physician believed that the primary lesion was in the appendix. Local suppuration does not complicate this disease. Excision of the diseased portion of the gut was followed by recovery in the five cases reported. With the exception of one case, in which recurrence was observed, the patients have remained well for from five to seven years. These results are certainly encouraging and speak well for Italian surgery.

Suppurative Parotitis.—Dr. Barjon, of Lyons, has just published a study on suppurative parotitis, a disease which is known to be quite rare. Ordinary mumps scarcely ever leads to the formation of abscess. The author, writing in the *Gazette Médicale de Paris*, No. 43, 1895, states that from his own observations, as well as from a careful examination of the literature of the subject, he is convinced that a secondary infection is needed to produce suppuration after mumps. He also asserts that bacteriological examination has shown the specific microbe of mumps to be non-pyoge-

nic. The only practical suggestion that can be made from Barjon's observations is to the effect that buccal antiseptics in mumps will positively prevent suppuration of the parotid glands.

Therapeutic Hints.

Rheumatism.—The associated pyrexia, dependent on bacillary invasion, is, when moderate, a favorable condition for checking its development and virulence, and constitutes in this, as in other like conditions, a determinant toward recovery—a way out of the disease. Tendency to relapses may be explained by renewed bacillary activity, new generations occurring, owing to inadequate or insufficiently prolonged specific treatment, or else to premature dieting with improper pabula, which favor the developmental activity of the infecting organism.—DUCKWORTH.

Flatulent Dyspepsia.—

Anæsthetic Tents.—Soak laminaria tents for eight days before using in

Ether.....35.
Iodoform.....10.
Cocaine (pure).....5.
—LEFOUR.

Gonorrhœal Rheumatism, when beginning. Fluid extract of jaborandi in half-teaspoonful doses every half-hour until four doses are taken.—HEATON.

Thyme, 100 grams, water 700, make an infusion and add syrup of marshmallow 50. Teaspoonful eight or twelve times daily for whooping-cough.—NOEVIUS.

Epilepsy.—Continue bromides after apparent cure. Their action suspends rather than cures the fits. Bromides are harmless and more easily tolerated than is usually believed. Frequent baths may prevent skin complications. FÉRÉ, *Rev. de Méd.*

Serum in Tuberculosis and Syphilis.—Serum of an animal inoculated with tuberculin always contains toxic principles. The milk of an animal inoculated with tuberculin is innocuous. Normal serum retards the progress of tuberculosis. Microbic serum can prevent its development. The serum of a dog inoculated eight days before with blood from a syphilitic, was inoculated in a woman suffering from nervous symptoms (tabetic). She had had syphilis twenty years before. After the injections the symptoms dis-

appeared. In a woman with syphilis of eighteen months' standing, who presented extensive ulcerations uninfluenced by specific treatment, seven injections of immunized dog serum reduced the ulcers to one-fifth their previous size.—RICHT, *Soc. de Biol.*

Acute Gastro-Enteritis of Infants.—Bismuth becomes particularly efficacious when associated with Colombo root. Colombo root, 1 gram, made into an infusion with 75 grams of water; to this when filtered is added subnitrate of bismuth, 3 grams and syrup of bitter orange peel, 15 grams. Dose: teaspoonful every two hours.—TRABANDT, *La Presse Méd.*, December, 1895.

Pulmonary Hysteria.—In this form of visceral hysteria, still but little known as affecting men, hæmoptysis is not at all influenced by ergotin, ice, astringents, etc. First treat the neurosis, and I believe much benefit can be derived from hypnotism.—LAURENT, *L'Indépendance Méd.*, December 11, 1895.

Tic Douloureux.—Neurotomy never gives lasting success. Give progressively increasing and subsequently decreasing doses of thebiac extract. The first day we gave our patient two pills, each containing two centigrams, and gradually raised the dose up to twenty centigrams, then slowly decreased to two and then stopping it entirely.—GILLES DE LA TOURETTE, *Indép. Médicale*, December 11, 1895.

Sulphur Baths simultaneously with mercurial frictions in the treatment of syphilis are supported by Grabowski (*Archiv für Dermatologie und Syphilis*, vol. xxxi., 1895), who is upheld by Kaposi and Finger. By this association greater quantities of mercury are said to penetrate the organism, while a salutary influence is exerted upon the nutritive processes of exchange. The frictions should be made some hours after the bath.

Guaiacol.—The antipyretic effect from external application is due to absorption by the skin of the vapor of the drug. If liquefied by gentle heat and painted over the chest wall with a small brush, the area being covered with adhesive plaster, a fall of from one to three degrees in temperature is noted. It can be employed in typhoid, febrile tuberculosis, etc.—BLAISE, *La Presse Méd.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, March 7, 1896.

THE INSANITY LAW.

THE Revision Committee has reported to the legislature of New York what they designate "The Insanity Law." It is a codification of all the laws relating to the insane, with many material changes. The first article relates to the State Commission in Lunacy and summarizes rather than elaborates the powers and duties of that body. In this respect American statutory law differs greatly and, we think, unfavorably from the English. Too much is left in our laws to the discretion of public officers.

We notice that while the *personnel* of the commission remains the same, provision is made that henceforth the medical member shall have "had five years' actual experience in the care and treatment of the insane, and is or has been a superintendent or first assistant physician of a State Hospital." We have frequently expressed the opinion that the tendency of the present Commission to destroy the autonomy of these great charities, and to centralize their management in a body which will always be under the control of partisan politics, is against public policy. This new phase of the law aims to strengthen and perpetuate that bureaucratic government of these Hospitals which has reduced the details of management to a lifeless, mechanical routine. It would be far better if the medical member of that Commission had been an experienced practitioner in the field of nervous diseases and had not been, previously to his appointment, inside of a State Hospital. He would detect, as no one trained in asylum methods could detect, the errors in the treatment of the insane in these institutions which result in such small percentages of recoveries. The great need of the State Hospitals to-day is a liberal transfusion into their management of the vitalizing intelligence and energy of the profession outside of asylum walls. The dead formalism of these Hospitals, which led an eminent alienist to characterize them as "great hospitals of lethargy," will only become more fixed and frigid by perpetuating that sort of medical "historic episcopate" which this clause in the bill provides.

But there is a much larger and more important interest involved in this proposed revised law which deserves the serious attention of the Legislature. It requires but a brief statement of facts to prove that the Lunacy Commission should now be entirely reorganized. When it was first created there were only about

five thousand insane in State care and a commission of three members was adequate to the duties required. With the recent transfer of the insane of all of the counties to State care the number has been increased to nearly twenty thousand, and the powers and duties of the Commission, as detailed in this bill, have been enormously increased. The number of insane now under the general jurisdiction of the Commission is nearly the same as it was in England when its famous Lunacy Commission was organized under the presidency of the Earl of Shaftesbury. That Commission consisted of eleven members. The Lunacy Commission of this State ought to be enlarged by the appointment of one commissioner from each State Hospital district, making a commission of eleven members. These commissioners should serve without pay, as do the members of the State Board of Charity, the Prisons Commission, and the State Board of Health. The interests of our State hospital system have now become so great, with its vast expenditure of public money, that every Hospital District should be represented in the Commission by a citizen of the most approved professional or business capacity. In view of the assumption by the State of the heavy financial obligation of caring for the twenty thousand dependent insane, a number which will now increase at the rate of one thousand yearly, the Legislature could not do a greater public service than to reorganize the Lunacy Commission in accordance with the plan above proposed.

The importance of enlarging and strengthening the *personnel* of the Commission becomes obvious when we consider some of the duties and powers which this law proposes to confer upon it. First, "The Commission is charged with the execution of the laws relating to the care, custody, and treatment of the insane." This is a duty and responsibility not conferred upon the English Commission, nor upon any similar body in this country or Europe. Second, the Commission has complete control of the acts of the boards of managers of all the hospitals. No by-laws, rules, or regulations in regard to the affairs of their respective institutions can be adopted unless approved by the Commission, and, that no act of the managers shall escape notice, the minutes and proceedings of all their meetings, and of their committees, must be sent forthwith to the Commission. Third, all the powers and duties of superintendents of hospitals are subject to regulations approved by the Commission. Fourth, the Commission has complete control of the expenditures of each hospital, which will involve in each year a total sum of upward of \$4,000,000. It also determines the number of resident officers and employees of the hospital and fixes the salaries and wages to be paid. When it is considered that the number of persons employed in these hospitals is upward of three thousand, and that the total expenditures will exceed \$4,000,000, the enormous responsibilities which this measure imposes upon the Commission can be appreciated. Sixth, we will mention but one more provision, which is as follows: "No contract executed by or for the benefit of any State hospital shall be valid without the approval of the Commission indorsed thereon." Thus the Commission becomes the medium through

which the contractor effects the sale of his goods to the Hospitals. It is only necessary to mention this feature of the bill. The dangers which lurk in it can be readily appreciated.

In conclusion we beg to submit to our legislators the importance of modifying the bill now before them, so as to meet conditions which evidently did not exist when the Revision Commission prepared it. Since that time New York county has added its quota of insane to those under State care, raising the grand total to nearly twenty thousand. The plan above outlined would be in harmony with the policy of the State in creating commissions, viz.: 1, One commissioner from each State hospital district, making eleven in all, that the interests of each district may be represented; 2, the commissioners serving without pay, as do the members of other State boards.

ANTI-VIVISECTION LEGISLATION.

It is becoming evident that there is a systematic and well-organized attempt on the part of many well-meaning and more foolish people who are interested in anti-vivisection agitation to secure legislation in the interests of their mistaken zoophilism. Bills have been introduced into the legislatures of Massachusetts, of New York, of several other States, and also in Congress. These bills are, for the most part, ingeniously framed in order to disarm criticism. In Massachusetts and New York, for example, the legislation desired is aimed apparently at prohibiting vivisection in schools and to confining vivisection, as is already done, to regularly incorporated universities, colleges, and medical schools. The bills, however, all contain one proviso, which, though apparently innocent, can really be used most effectively against biological research. This proviso is one making it permissible or obligatory for an agent of some society for the prevention of cruelty to animals to be present during vivisection experiments, wherever held. In a circular drawn up by a committee of the Massachusetts Medical Society and signed by its president, Dr. F. K. Paddock, by the chairman of the State Board of Health, Dr. Walcott, and by Drs. T. H. Gage, S. D. Presbrey, and Professor Bowditch, the real significance of this proviso is shown in the following paragraphs:

"Legislation of this sort will of course seriously hamper and may even practically abolish biological and medical research throughout the State, for self-respecting investigators will scarcely consent to work under a penal act administered through the agency of a society the members of which are for the most part wanting in that special training which alone could fit them to understand the importance of an experiment for the advancement of medical science or qualify them to judge whether suffering is or is not inflicted.

"Experience has shown that it is never safe to assume that proposed legislation can be so obviously mischievous that opposition to it is unnecessary. You are, therefore, urgently requested to communicate at once with your representatives in the legislature. Explain to them that from the time when Harvey discov-

ered the circulation of the blood 'by frequently looking into many and various living animals' down to the present day, when the discovery of the antitoxin treatment has robbed diphtheria of almost all its terrors, nearly every important advance in medicine has been rendered possible by knowledge acquired through the careful study of the phenomena of life as revealed by what are popularly known as 'vivisections.' Point out to them that such investigations are at present conducted with every precaution against unnecessary suffering and by men who do not admit for a moment the claim of any society to be actuated by motives more humane than those by which they themselves are guided, and that, as there is no abuse to be corrected, the proposed legislation is totally uncalled for."

THE MALE TRAINED NURSE.

ONE of the daily papers devotes a column to the subject of training men for nurses, and gives a very glowing picture of the career of the male trained nurse. We are informed that more than four hundred applicants for positions in the New York Training-School for Male Nurses were turned away last year, and that the popularity of the profession is increasing. The newspaper account also says that none of the trained nurses make less than \$40 a week, and the best frequently earn from \$80 to \$100. We are even told that many medical students select this profession rather than undertake the practice of medicine. Our contemporary makes one further statement, which we can confirm with hearty emphasis, namely, that there are not more than a dozen really good and competent male nurses in the city to-day. Some might go even farther and say that there is no such thing as a good trained male nurse, but this is, perhaps, somewhat too radical. The fact is, however, that men do not make good trained nurses, and they are merely tolerated as necessary evils by those members of the profession who recommend their employment. There are certain classes of cases which men alone can properly manage, and for this reason there must be trained male nurses. The profession is, therefore, a legitimate and useful one, but the range of usefulness is not very wide and the field is not a great one. The qualities which make a man a good trained nurse are such as would usually make him a more successful worker in a pleasanter field. Therefore the most desirable men rarely continue long in this profession; indeed, many of them use it simply as a stepping-stone to graduating in medicine later. While male nurses do get large wages, their employment is not certain, they often have long periods of inactivity, and this irregularity of employment tends to irregularities and intemperance in living.

The Maryland Medical Journal is responsible for the statement that out of the three thousand doctors in New York City only six hundred were born in this country. How this information was secured we do not know, but it does not appear to us to represent the truth. We should say rather that about six hundred were not born in this country.

SHEDDING OF THE SKIN.

It is a well-known fact that after severe dermatitis, such as that occasioned in susceptible subjects by the use of quinine and other drugs and at times by other causes, epidermic casts of the hands and feet have been observed. Any severe inflammation of the surface is apt to result in general desquamation, and this now and then may take the form of large flakes or sheets of dead scarfskin. It is seldom, however, that one meets with an account of such extensive peeling and of such perfect casts as that given in the *Florida Times-Union*, February 23, 1896.

A boy six years of age stuck an orange thorn into his hip, causing a severe inflammation followed by a swelling of the whole body, which reached decided proportions. When the swelling subsided and recovery took place, according to the report, almost immediately after this "the skin began to flake off in strips and patches until he had completely shed his entire cuticle, as a snake at moulting-time, including that over the palms of his hands and soles of his feet, which came off whole and resembled somewhat a cast-off shoe, being quite as hard and thick. There is a perfect cast of each of the feet, showing the lines of the skin, and it has about the consistency and much of the appearance of a thin layer of dried glue."

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

THE *Columbus Medical Journal*, in noticing the announcement of the next meeting of the Congress of American Physicians and Surgeons, comments on the fact that all the officers of the executive committee live in the East, and that neither the Sunny South, the Great Northwest, the Land of the Setting Sun, the Mississippi Valley, or the Great Divide have received any recognition. The *Journal* should remember that, after all, these are only officers of the executive committee, and that the officers who head the different sections and who organize the scientific work will, no doubt, show a much wider geographical distribution. Even if this were not so, we see no reason why the congress should not be called "American," for New York and the other States represented may still be considered as American commonwealths. If we chose to be captious ourselves, we might, in the same way, turn to the records of the meeting of the American Medical Association and call attention to the fact that hardly any of its officers represent the East and that especially few come from the State of New York, which contains one-sixth of the population of the United States. Yet we do not wish to call the American Medical Association a "Western Medical Association." The fact is, both the association and the congress have proper fields for work, and they need not in any wise antagonize each other. We hope there will never be any Schomburgk line among American medical associations.

Dr. M. Armand Ruffer has been appointed professor of bacteriology at the medical school of Cairo.

News of the Week.

Influenza is reported to be epidemic at Paulsboro, N. J. Pneumonia also is quite prevalent, though of mild type. Children especially are the victims.

The Charles Carroll Lee Ward.—The directors of the Post-Graduate Medical School and Hospital have named one of their wards in memory of the late Dr. Charles Carroll Lee, who was for many years a professor in the institution. They have placed a tablet in the ward, giving the names of those who combined to contribute the ten thousand dollars which was required for the purpose of the memorial. These names are as follows: Dr. Robert Abbe, Dr. L. Bolton Bangs, Mrs. James Beales, Dr. Stephen S. Burt, Miss Caldwell, Dr. Charles L. Dana, Dr. Bache McE. Emmet, Dr. George H. Fox, "A Friend," Dr. Horace T. Hanks, Mr. and Mrs. Eugene Kelly, Mr. and Mrs. Henry J. Lamarche, Dr. Daniel Lewis, Mr. and Mrs. William Lummis, Mr. and Mrs. Frank A. Otis, Dr. Clarence C. Rice, Mr. Eli K. Robinson, Mr. Nelson Robinson, Dr. D. B. St. John Roosa, Mrs. Eliza M. Sloan, Dr. Andrew H. Smith, Mrs. M. E. Sparks, Dr. Reynold W. Wilcox. It will be seen that the faculty of the institution participated largely in the memorial gift.

Mortality in New York State.—The bulletin of the Board of Health of the State for the month of January shows that there were 10,176 deaths reported during the month, and an estimated death rate of 18.50, there having been an average daily mortality of 328 against one of 305 in December and of 354 in January, 1895. Compared with the preceding month there was an increase in mortality from scarlet fever, measles, and cerebro-spinal meningitis, and a small decrease in that from typhoid fever and diphtheria. Compared with January, 1895, there were considerably more deaths from scarlet fever, measles, and typhoid fever. Consumption caused 100 more deaths than in December, but 100 fewer than in January of last year. Acute respiratory diseases caused 2,000 deaths, an increase of 250 over December, but 570 less than in January, 1895, and less than in this month for five years. There were 687 reported deaths from diseases of the urinary system, which is an unusual number. Other local diseases caused about the same mortality as in December. The large increase in mortality which for several years has been reported in January over December, due to grippe, has not occurred, and the usual annual occurrence of grippe, which appears to have set in in December, has been far milder than any of the series, not more than 500 deaths being attributable to it this month. There has been a remarkable epidemic of jaundice in the Hudson Valley district, and the reports of death from jaundice elsewhere in the State indicate its probable more widespread distribution.

Dr. Walter F. Chappell writes: "My attention has just been called to the MEDICAL RECORD's report of my remarks at the academy on 'Laryngeal Tuberculosis.' I am made to say that I cured two cases after

three weeks' treatment. I said I had succeeded in arresting the disease in two cases after three months' treatment. Laryngeal tuberculosis is such a terrible disease that I fear my veracity will be questioned if it goes forth that I claim a cure in that short time."

State Board of Undertakers.—The undertakers, usually so demonstratively meek and with a business training calculated to repress outbursts of temper, are now clamoring for a State board of control for the higher and more æsthetic performance of their various and lugubriously officious duties. None but qualified practitioners are to be admitted to the guild. Each applicant must stand the test of an examination, mental, physical, and moral, for the obvious reason that the corpse is forced "by circumstances over which he has no control" to rely entirely on the ability of the practitioner to make him a properly presentable object lesson to the mourners.

Prevention of Tuberculosis.—At a joint meeting of the State Board of Health and the New York City Board of Health, held on February 28th, a committee was appointed to draw up a petition to be submitted to the legislature and the government, explaining the importance of the tuberculosis question and asking for a larger appropriation to crush out the disease. The committee appointed consists of Mr. Wilson and Drs. Prudden, Fowler, and Biggs.

The Manhattan State Hospital.—The New York City Insane Asylum passed under the care of the State last month and on February 28th became legally the Manhattan State Hospital. The reports state that some friction has already developed between the city and the State authorities. The superintendent issued an edict that no patient sent from the city to the Manhattan Hospital should be received unless he had been supplied with a new suit of clothes and underwear, this being a measure intended to save expense to the State and to prevent the introduction of contagion. As it was impossible to supply new suits of clothes at once, the charity commissioners, upon the advice of the corporation counsel, secured a mandamus compelling the State hospital to receive the patients.

"Skiagraph" is the best name that has yet been suggested for the process of photographing by the "X" rays. The term "radiograph," which has been considerably used, is utterly wrong etymologically. The Anglicized expression, "shadowgraph," is one which is sufficiently justifiable and, since it still appears that the process is one done by rays having the nature of light, the term "photograph" is not an incorrect one.

The "X" Rays.—The *British Medical Journal* for February 22d gives a very good reproduction of a photograph of an injected kidney and of the injected vessels of the hand.

Discovery by Means of the "X" Rays of a Bullet Lost in the Wrist.—Mr. Robert Jones and Prof. Oliver Lodge, of Liverpool, report in *The Lancet* the case of a boy, twelve years of age, who had shot himself in the left hand just above the deep palmar arch.

The bullet could not be found except by injudicious probing; therefore a "skiagraph" was taken, and the position of the foreign body accurately determined by it.

Penetration of Bone by Roentgen Rays.—DR. W. J. MORTON, of this city, has succeeded by the Roentgen rays in locating a needle embedded in the fleshy part of the ball of the foot and behind the bone, demonstrating the fact that the bones may be penetrated by the Roentgen radiation, so that metallic objects within and behind said bones may be pictured. The case will be reported in our next issue.

A School of Medicine for Women, at St. Petersburg, has already an annual grant of \$50,000 from the government and of \$12,000 from the city, while from private sources the sum of \$360,000 has been raised. With this money there certainly should be established an excellent medical school for women.

The Texas State Medical Association is to meet at Fort Worth on April 24th, and it is pleasant to learn from the *Texas Medical News* that there will be no "scrapping" there this year. A committee is to report upon "harmony" and "medical legislation." The Texas doctors want two things: first, a law regulating the practice of medicine, and second, a State board of health. We have great faith that the Texas doctors will get what they want or else the fur will fly.

Hospitals and Tuberculosis.—Professor Jaccoud has come out with an emphatic statement to the effect that tuberculosis is not communicable from tuberculous to healthy patients in hospitals, and he asserts that in all cases of alleged consumption the victims had previously local tuberculosis.

The Effect of Cemeteries upon Health is a subject that has been frequently discussed by the advocates of cremation, just as the effects of health upon cemeteries have been frequently discussed by the medical profession in general. Professor Petri, of Berlin (*Boston Medical and Surgical Journal*), some time ago stated that no ill effects are traced to cemeteries, provided they are properly conducted. The matter has again been tested by the Imperial Board of Health of Germany, the work having been entrusted to Dr. Losener. He found that in the buried cadaver typhoid bacilli were found only up to the 96th day after burial; cholera germs lived 28 days; tubercle bacilli 95 days; tetanus bacilli 234 days; anthrax germs a full year. Dr. Losener concludes that Petri's observations are correct, and that even wetting of graves by soil water in porous soil does no harm, provided this soil is surrounded by good filtering material of the ordinary character.

Switzerland is rapidly becoming a centre for temperance agitation. One of the most unique manifestations of this is an appeal from the Swiss students to the French students to abstain from excess in alcoholic drinks.

The Medical Record's Thirtieth Birthday.—The MEDICAL RECORD completed its thirtieth year on Saturday last, the first number having been issued March 1, 1866.

Prof. Lewis A. Sayre's Nineteenth Birthday.—Our distinguished townsman, Prof. Lewis A. Sayre, although seventy-six years of age on Saturday last, had reached at that time but his nineteenth birthday, it coming only in leap years or on February 29th. When Professor Sayre celebrated his eighteenth birthday in 1892, the Rev. Dr. William R. Huntington, pastor of Grace Church, sent him the following poem:

"Dear Doctor Sayre, and is it true,
That Nature set her clock for you
Some four and fifty years too slow?
How clever of her to foreknow
That you would keep yourself so young,
So firm of heart, so stout of lung;
That she would never be detected,
Or you so much as e'en suspected
Of being older by a day
Than leap-year records seem to say!
Eighteen, dear friend, or seventy-two,
Which e'er it be, good luck to you!"

"So say we all of us." Thousands of his professional brethren on both sides of the Atlantic, his numerous friends and patients, and all his old associates wish him many returns. Few are privileged to get the better of their birthdays in this way and receive the twice-doubled congratulations that attend them. You are welcome to all, old friend. Smell the flowers while you can.

The Late Dr. Cornelius G. Comegys, who died recently at Cincinnati, was a son of Cornelius P. Comegys, who was governor of the State of Delaware from 1837 to 1841. Dr. Comegys was graduated from the University of Pennsylvania in the year 1848 and began the practice of medicine in Cincinnati, where in 1849 he rendered excellent service during an outbreak of cholera. At the organization of McMicken University, now the University of Cincinnati, he was elected a trustee and served continuously in that capacity until up to the time of his death and for a number of years as president of the board.

"**Knockout Drops**," so called, and such as are mixed with liquors to produce a stupefying effect, are said to be composed of chloral hydrate in the proportion of ten grains of the drug to a teaspoonful of water and can be purchased at many drug stores without a physician's prescription, as shown by a reporter of the *New York Sunday Journal*.

New York's Death Rate.—For the week ending at noon February 29th there were 893 deaths in the city, 335 being in cases of children under five years old. The causes of death were: Measles, 21; scarlet fever, 16; diphtheria, 47; whooping-cough, 8; typhoid fever, 5; malarial fever, 2; meningitis, 3; diarrhoea, 11; heart disease, 35; croup, 6; bronchitis, 36; pneumonia, 161; phthisis, 95; Bright's disease, 73; violence, 70; other causes not given.

A New Inspector for Barren Island.—The State Board of Health at its recent meeting in this city decided to revise the rules governing the inspection of factories on Barren Island and also to dispense with the services of Inspector Arthur Hollick after April

1st. Upon the recommendation of President Daniel Lewis, Orville Lewis was appointed in Hollick's stead. The place carries a salary of \$5,000 a year. The new appointee is a relative of Dr. Lewis.

Shadow Pictures of Soft Tissues by Roentgen's Rays.—Dr. H. L. Smith, of Boston, using a faradic battery, has, it is said, succeeded in photographing the soft tissues of the body and in making "shadow-graphs" of the intestines.

The German Dispensary.—At the last scientific meeting of the attending physician to the German Dispensary, February 18, 1896, Dr. F. Schwyzer read a paper on "Blood Diagnostics and Some of the Recent Important Discoveries in this Field." During the dinner following the meeting a loving-cup was presented to Dr. Ludwig Straus in recognition of his twenty-five years' service in the German Dispensary.

Proposed New Acts of the Legislature of the State of New York.—A bill has been introduced making it lawful for town boards of any town in which a hospital giving gratuitous treatment is situated to include in its annual tax levy a sum not exceeding \$1,500 in any one year for the benefit of such hospital. Also a bill forbidding the cutting and sale of ice for family or domestic purposes from any river. This is a sweeping measure and is hardly likely to be passed. Also a bill relating to licensing for the practice of pharmacy, requiring four years' experience or certificate from any licensed board of pharmacy. Also a bill specially relating to the counties of Onondaga, Oswego, Madison, and Cortland and to the warden of Auburn State Prison, in relation to the disposition of corpses in the public institutions of said counties and providing for the obtaining of cadavers by educational institutions.

Increase of Tuition Fee in the University of Pennsylvania.—Philadelphia may well be proud of her University of Pennsylvania and the medical profession of its medical department. The last dozen years have marked a wonderful advance in the growth and development of this institution, which promises to be surpassed only by its future achievements. The increased and increasing importance of the university has given it a foremost place among the great colleges of this country. Reference has been made previously to certain changes having in view the elevation of the standards of entrance requirements in the medical school and concerning which further information has been given out. Among other things it has been proposed to raise the tuition fee from \$150 to \$200 per annum, the same that is charged by the medical department of Harvard University and by the College of Physicians and Surgeons of New York. Heretofore graduates from medical schools requiring attendance upon three courses of lectures in different years were allowed to enter the fourth-year class of the university upon passing an examination in therapeutics and obstetrics. Hereafter, however, such students, as well as those who have attended three courses of lectures in schools requiring four years of attendance, will be obliged to pass examinations in general and medical

chemistry, materia medica and pharmacy, the elements of general pathology, the entire subjects of anatomy and physiology, applied anatomy, general and special pathological anatomy, therapeutics, surgery, obstetrics, and gynecology. Graduates of four-year schools will be admitted to the fourth-year class upon passing examinations in therapeutics, pathology, and obstetrics. Graduates in pharmacy and dentistry, who have hitherto been admitted to the second-year class upon condition of making up during the year certain first-year studies, must hereafter take the examinations required for entrance into the freshman class.

The New York State Civil Service Commission finds great difficulty in securing suitable candidates for the position of woman physician in the State hospitals. The position is a desirable one, paying from \$1,000 to \$1,500 per year, besides giving ample opportunity for practice and study in nervous and mental diseases, with pleasant home and associations. The examination advertised in January failed for lack of applicants. Application for this examination should be made to the secretary of the State Civil Service Commission at Albany.

Effect of Ovariectomy on the Nervous System.—A correspondent asks in how large a percentage of cases can it be fairly said that ovariectomy makes a nervous wreck of a woman?

A Stricken Town.—The daily papers report that in the village of Basking Ridge, N. J., which has a population of about three hundred, a large proportion of the inhabitants are sick with either measles, diphtheria, or typhoid fever. Within the last seven days there have been 9 deaths—1 from diphtheria, 3 from typhoid fever, and 5 from measles. The fever epidemic is said to have originated from foul water, and an officer of the State Board of Health who examined the water ordered four of the wells closed. The three physicians are very much overworked. Trained nurses are helping them.

Diphtheria Antitoxin in Chicago.—Of 629 cases of diphtheria treated in Chicago with antitoxin 591 recovered; 38, or six per cent. of the whole number, died, but there were no deaths among the cases treated within twenty-four hours after the disease had made its appearance. Of 437 persons exposed to contagion and immunized, not one contracted the disease.

The Successors of Verneuil.—Dr. E. Monod has been elected to the section on surgical pathology of the Paris Academy of Medicine to fill the vacancy created by the death of Verneuil, and Dr. Lannelongue has been chosen to fill the vacancy in the Academy of Sciences arising from the same cause.

Pennsylvania State Board of Medical Examiners.—Dr. A. H. Hulsizer has been reappointed by the governor a member of the State Board of Medical Examiners.

Epidemics in Western New York.—Many of the schools in Wayne County, N. Y., have been closed on account of the prevalence of scarlatina and diphtheria.

Throughout the entire county there are many cases of these diseases, and reports made by registers of vital statistics throughout Wayne County show a large increase in the mortality rate, deaths being due principally to throat and lung disorders and scarlet fever.

Stray Animals as Carriers of Disease.—In a recent address President Haynes, of the New York Society for the Prevention of Cruelty to Animals, called attention to the fact that nearly all stray animals are diseased and therefore a continual danger to healthy animals. "But that is not the only danger," he said, for "human diseases are undoubtedly propagated in the same way. In cases of diphtheria, small-pox, scarlet fever, measles, and diseases of the skin in general, no disinfection of houses or rooms can be effectual if dogs and cats which inhabit them are not likewise disinfected; and in the opinion of many competent physicians the spread of contagious diseases must be in many instances attributed to this cause."

Eye Strain.—A most interesting paper on "The Disabilities Due to Eye Strain," as viewed by the general physician and by the ophthalmologist, was read by Dr. S. Weir Mitchell at a recent meeting of the section of ophthalmology of the College of Physicians. The case was detailed at length of an able lawyer and important man of affairs whose life was made miserable and whose usefulness was impaired by reason of derangement of balance of the external ocular muscles to such an aggravated degree as to induce intense headache for long periods, during which he was incapacitated from work. Treatment at the hands of distinguished ophthalmologists with lenses, prisms, and tenotomy yielded only transitory benefit, the distressing symptoms returning after each period of comparative relief. An interesting "Discussion on the Subject of Intracranial Tumors," participated in by Drs. Mills, Lloyd, Dercum, Norris, de Schweinitz, Thomson, Keen, and Da Costa, took place at a special meeting of the college on February 19th, and while little that is new was brought out the consideration of the subject in its various aspects proved most instructive.

Sale of Quinine in Tobacco Shops.—A bill has been introduced into the Italian Chamber of Deputies to add quinine to the other government monopolies of salt and tobacco, and to confine its sale to those who have a government permit. If this became a law the druggists would be forbidden to sell the drug and those who wanted it would be obliged to procure it from a tobacconist.

Destroyed a Hospital.—The *Diario de la Marina* of Havana contains an account of the destruction of a hospital by the Spanish troops in Cuba. The eight patients, wounded insurgents, escaped, but the Spaniards captured the hospital and destroyed it, after taking away the instruments, medicine chest, and other portable property.

Tuberculosis in Paris.—The proportion of deaths from tuberculosis in Paris is 490 per 100,000 inhabitants. In the Department of the Seine, whose population, including that of Paris, numbers over three mil-

lion, the average mortality from tuberculosis, during the period comprised between 1889 and 1893, was 14.565.

A Prohibitive Tax on Cigarettes.—The South Carolina House of Representatives, in keeping with its other vagaries, has passed a bill imposing a tax of twenty-five cents on each package of ten cigarettes sold in the State, with a proportionate tax on a larger number.

The Plague is reported to have reappeared in the native quarter of Hong-Kong. There have been many deaths from this cause within the past few weeks.

Maragliano's Tuberculosis Antitoxin.—Dr. de Renzi, of Naples, reports that in twenty-two cases where he has used Maragliano's treatment for tuberculosis he has found a distinct improvement and that in some he has cured the disease.

Bacteriological Work of Philadelphia Health Board.—The report of Dr. B. Meade Bolton, the chief of the bacteriological division of the Philadelphia board of health upon the work of his department from the time of its organization, May 20, 1895, to the end of last year, contains some interesting information. During this period 3,363 cultures were made and studied, 215 with negative and 1,207 with positive results. The last occasioned 1,942 secondary cultures. Of the 1,207 cases diphtheria bacilli were found in 775. A clinical diagnosis was made by the attending physicians in 705 cases, of diphtheria in 557, which was confirmed in 502 by bacteriological examination. In 460 cases in which diphtheria bacilli were found the interval from the beginning of the disease to the disappearance of the bacilli varied from 7 to 96 days, the average being 28.3 days. The division has not yet issued diphtheria antitoxin for distribution because a serum of sufficient strength has not thus far been secured. According to the report of Dr. William M. Welch, the physician in charge of the Municipal Hospital, whose service is restricted to the care and treatment of contagious diseases, 1,297 patients were received during last year, 757 of whom suffered from diphtheria. The antitoxin was employed in the treatment of 302 of the last named, 85 of whom died, a mortality of 28.14 per cent. Among the cases treated without the antitoxin the mortality was 25.99 per cent.

Dental and Medical Students at War.—The students of the Philadelphia Dental College and those of the Medico-Chirurgical College attend lectures in the same building but do not dwell together in unity. The bad feeling culminated a few days ago in a pitched battle between a number of the students of each institution. The encounter took place in one of the halls and became so serious that a squad of police was called in to stop the disturbance. One medical student was knocked down and rendered unconscious and several others were more or less seriously injured.

The London Death Rate.—The number of deaths in London last year was 85,138, equal to an annual rate of 19.4 per 1,000, the population being about 4,392,000.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the Medical Corps of the U. S. Navy for the week ending February 22, 1896. February 19th.—Medical Director P. S. Wales placed on the retired list from February 27th; Surgeon D. M. Guiteras detached from the *Montgomery* and granted six months' sick leave; Passed Assistant Surgeon L. W. Curtis detached from duty at Indian Head Proving Ground and ordered to the *Montgomery*; Assistant Surgeon L. Morris detached from the Naval Hospital at Philadelphia and ordered to the Indian Head Proving Ground. February 21st.—Medical Inspector Dwight Dickinson ordered as member of the retiring board, February 28th.

Changes in the Medical Corps of the U. S. Navy for the week ending February 29, 1896. February 27th.—Assistant Surgeon J. C. Rosenbleuth, detached from the Naval Laboratory and ordered to the *Raleigh*. Assistant Surgeon E. M. Shipp, detached from the *Raleigh* and ordered to the *Vermont*.

Preparatory Medical Education.—Another bill whose object is to change the present medical law, and known as the Stanchfield bill, is now before the Assembly at Albany. The bill aims to change the requirements for preparatory medical study, so as virtually to remove these requirements altogether; that is to say, the law will name the general subjects in which proposed medical students shall be examined by the faculties of the different colleges, but the amount of knowledge upon these subjects which such students must possess will be determined by the faculties of the medical schools. Some of our medical colleges assert that the present law does not secure any higher grade of education among medical students by reason of its provision for preliminary medical education, but that, on the other hand, it tends to drive medical students from the State. *À propos* of this question, Drs. A. Walter Suiter, M. J. Lewi, and J. M. Winfield, the committee on legislation of the New York State Medical Society, have sent a communication to the members of the society throughout the State, in which they say:

"Should this bill become a law, preliminary education of medical students, on which New York has justly prided itself, will become a farce. Our State Medical Society year after year has protested against any such change in the law, and has warmly supported the existing protections against incompetence in practitioners, or against mercenary motives in those who would make cheap the degree of M.D. There would be little objection to the four-year course proposed were it added to the existing law, but here it seems designed chiefly to cover up and carry 'riders' against which the best medical sentiment of the State will be unanimous.

"You will note that Section 2, while naming several studies for examination, prescribes no standards for passing, and thus leaves every medical school absolutely free to matriculate every applicant who goes through the form of an examination.

"Section 3 is so worded that any one put on the list of matriculants by any medical school becomes ex-

empt from examination, and each matriculating officer is left free to determine for himself what are reputable colleges or high schools of the first grade, thus evading entirely any State control of standards.

"Section 5 does away with all the safeguards as to age, moral character, and satisfactory instruction that have been provided, after a generation of study and experience, by those having at heart the best interests of the medical profession in New York.

"Section 6 wipes away the restrictions for matriculants till next year, while Section 7, under an indefinite blanket clause, can be construed as authorizing the disregard of many of the most essential features of our present wholesome laws."

Small-Pox in London.—The cases of small-pox notified in London during 1895 were 979, against 2,813 and 1,192 in the two preceding years.

The Nose as a Microbe Destroyer.—According to some recent experiments there are in each particular pint of air which the adult takes in with inspiration about 15,000 microbes. In some localities, to be sure, this number reaches up to the million, but the average city number is about as stated. This microbe-laden air is taken into the air passages. When the air is thrown out it is quite sterile. The air has further been found to be sterile in the naso-pharyngeal cavity. The inference is, therefore, that the nose is a most powerful microbe destroyer, and also that, in order to destroy the individual 15,000 microbes, it is important to draw the air through the nasal passages.

Serum Therapy per Rectum.—M. Chantemesse states that the immunizing serums can be employed in the form of enemata with the same result as when given subcutaneously.

Prof. Cesare Lombroso, who has long held the chair of legal medicine in the university of Turin, has been made ordinary professor of psychiatry in the same school.

Vivisection in the Public Schools.—A bill to prohibit vivisection in the public schools is now before the legislature at Albany. One of the advocates asserted that "Jack the Ripper" was an example of the modern vivisectionist.

"Inherited Surgical Dilettantism."—In Paris a man recently appealed against a sentence of two years' imprisonment passed on him for cutting off children's ears. He would go up to a boy in a lonely place and say to him: "What's the matter with your ear? It's bleeding. Just let me see it." Then he would take hold of the ear and with a razor which he carried concealed in his coatsleeve, cut off as much of it as he could—in some cases the lobe only, in others the whole ear. On the appeal it was stated that his father and grandfather were employed in dissecting-rooms. On his behalf his counsel pleaded mania and that he suffered from inherited surgical dilettantism. In the result the tribunal added three years to the original sentence.

Cobra Bite Cured by Serum Therapy.—Some of M. Chalmette's prepared serum for the treatment of snake bite had been sent from the Pasteur Institute to Mr. Hankin, the government bacteriologist at Agra. It has recently been used by him with success. A native bitten by a cobra was cured, and a number of sheep poisoned with snake venom were also saved from destruction. The serum is the result of a long series of experimental investigation involving vivisection.

The Insane of Massachusetts under Supervision at the end of the year 1895 were 6,768, of whom 5,763 were in asylums and hospitals, 803 in town almshouses and in many cases not only not receiving suitable care but sometimes even being cruelly neglected, and 202 in private families. During the year acts of the legislature have been passed establishing an asylum for insane criminals and a hospital for epileptics.

The Fourth Session of the Obstetrical Society of France will be held in Paris from the 9th to the 11th of April next. The following are the subjects for discussion: (1) "Artificial Dilatation of the Os Uteri at the End of Pregnancy or During Labor," and (2) "Treatment of Post-Partum Hemorrhage."

Addison's Disease.—Dr. Osler reports a case of Addison's disease greatly benefited by the use of suprarenal extract.

The Denver Health Department.—At the meeting of the Denver and Arapahoe Medical Society held January 28, 1896, the following resolutions were passed:

"*Whereas*, The death rate in Denver has, within five years, been lowered about one-half; and

"*Whereas*, It cannot be reasonably doubted that this extraordinary reduction has been due to the active and intelligent administration of the public health service; and

"*Whereas*, The medical profession is in a position to assert the great aid to the prevention of disease and the saving of life afforded by the health department through the application of modern methods, particularly as regards bacteriological procedures; be it

"*Resolved*, That we, the Denver and Arapahoe Medical Society, view with alarm the crippling of the efficiency of the health department which must follow the reduction of its appropriation to a sum inadequate, not only to accomplish its desirable development but even to support its present staff of workers."

Vivisector and Philanthropist.—In speaking of Professor Ludwig, one of the most persistent of vivisectors. Dr. Mosso says: "Ludwig, the greatest of vivisectors, was president of the Leipsic Society for the Protection of Animals, and remained to the last one of its most active members. Germany owes it to him that her horses and beasts of burden are now humanely treated. To him is due the awakening of the true humanitarian spirit toward the brute creation that culminated in the 'Union of German Societies for the Protection of Animals.'"

The Post-Graduate School of Medicine of the District.—The act of Congress incorporating the Post-Graduate School of Medicine of the District of Columbia, which passed both houses, was signed by the President on the 7th instant and has consequently become a part of the revised statutes. The school is allowed to hold real and personal property to the amount of \$200,000. The course of teaching has been arranged and the school will be in operation shortly.

The Question of the Temperature of Vaginal Injections.—The *Leeds Evening Express* contains the report of a case tried in the Leeds County court, England, in which the principal question at issue was whether or not water of too high a temperature had been used by a medical man as a vaginal douche in the treatment of hemorrhage. Several witnesses swore that they asked the medical man if the water was not too hot and he made no reply. The witness who gave him the water swore that it was boiling and that she had told the medical man so. As a matter of fact, some large blisters appeared subsequently on the patient's body, and it was alleged that they were produced by the excessively hot water used. The county court judge found that the water used was scalding and not fit to use, and that it did cause the injuries complained of. He did not find that it was necessary to use such hot water to save the woman's life. He held that the medical man was guilty of malpractice because he did not observe that the water was scalding, and damages to the extent of £15, less the medical man's claim of £3 10s. for medical attendance, were awarded. The patient was suffering from post-partum hemorrhage.

Doctors Should Not be so Modest.—I know that there is a general feeling among physicians of the better sort that conspicuous interest in public affairs may be misconstrued and looked upon as in some sort a means of professional advertisement. And one cannot choose but to appreciate and admire the sensitiveness and high sense of honor of which this sentiment is born. But, after all, there are greater misfortunes in life than being misunderstood, and I think that the fine feeling which leads the physician so often to waive the privileges of social and public life in the interest of what he conceives to be professional ethics is capable of a richer fruitage yet, in the defiance of misconception, when impelled to whatever performance of public duty he can justify to himself.—*Dr. T. Mitchell Prudden, Address before Yale Medical School.*

Hypnotism on Exhibition.—At the Royal Aquarium, London, a man is shown in a condition of trance produced by hypnotism, in which state it is proposed to keep him for thirty days, more than twenty having already passed. The subject is twenty-nine years old and a well-built man; he was, when seen, lying flat on his back with his limbs stretched out in an easy position and his head turned a little to the right. His face was pale, with a slight pink flush on each cheek, and his appearance gave the observer the impression of a man who had been ill for some time.

His pulse was 52, quite regular, and of fair tension. Respirations were chiefly abdominal, and were eight to the minute and regular. Occasionally he gave one or two deep sighs like a man about to wake, and in these the thorax was more actively moved. His larynx was occasionally raised as the act of swallowing was involuntarily performed. Slight twitching of the eyelids and an occasional twitch of the legs were the only visible movements. The eyes were closed, and on opening them the eyeball was turned upward and outward and the pupil was dilated. His temperature was recorded to have been 97.2° F. He is fed with peptonized milk through a tube, and it was said that he is getting about a pint a day. The above is a short description of the performance, which is conducted as a public exhibition. At stated intervals in the day the hypnotist gives lectures on the subject and demonstrates the insensibility of the man to an admiring audience, and in his absence an assistant takes charge. A medical man also sees the subject at intervals and signs bulletins as to his condition.

Medical Men and Matrimony.—Doctors, like other men, are apt to rush into matrimony with as light a heart as M. Ollivier entered on the Franco-German war, and sometimes with almost equally disastrous results. No amount of good advice is likely to prevent this, for the voice of reason has little chance of making itself heard amid the whirlwind of passion. The students of the Rush Medical College, Chicago, may, therefore, be congratulated on their good sense in asking the advice of their teachers on the question of marriage, and the latter may equally be congratulated on their tact in giving advice which is in accord with the inclination of the "average sensual man," and is therefore pretty sure to be followed. The deliverances of the oracles are published in the January number of *The Corpuscle*, a journal edited by the students of the Rush College. The professors are unanimous in pronouncing that *Punch's* famous advice "to those about to marry" does not apply to doctors. It is imperative, says Dr. Haines, that doctors and clergymen should be married men "by reason of the relations which they sustain to the gentler sex." On the question of time too there is practical agreement that the sooner a young practitioner takes unto himself a wife the better it is for his professional prospects, and that he will do well in this matter not to let "I dare not" wait too long upon "I would." Prof. Henry M. Lyman, indeed, counsels prudence to the young man who has his way to make, and urges him "to fit up an attractive office and supply himself with the necessary books and instruments for the efficient practice of his profession before undertaking to invest in the paraphernalia of a feminine wardrobe." Dr. E. L. Holmes says "the young physician should wait till he has at least an income sufficient for his own support," and Dr. Fletcher Ingals insists on this with "one hundred and fifty per cent. more on which to support a wife." Dr. Cassius D. Westcott, on the other hand, testifies that "a good wife will help a doc-

tor to provide a home for two almost as he can provide for himself alone;" and Dr. James B. Herrick opines that "many a woman will be a positive saving in cash, a good financial investment." To Dr. D. R. Brower's mind "finances cut little or no figure in the matter," and indeed nothing is more remarkable in the "symposium" than the idyllic view of life taken by the professors of the Rush College. Their noble sentiments make us proud of our profession. Prof. J. M. Dodson does, indeed, hint that if the bride has an income of her own, the young doctor should not "allow a false sense of delicacy and a foolish determination to be independent to postpone her happiness and his own." The other counsellors, however, are careful not to dim the brightness of love's young dream with any whisper about the prospective father-in-law's bank book.—*British Medical Journal*.

The Effect of the "X" Rays upon Micro-Organisms.—The assertion that the "X" rays may have some therapeutic value, and may perhaps modify the course of disease when passed through the body, has been made by a number of persons and it is a claim which may easily be misused by the charlatan. Dr. T. G. Lyon, of London, recently made some experiments on the influence of these rays on cultivations of diphtheria bacilli. They were exposed in the incubators for twelve hours to the "X" rays. The bacilli continued to grow and were not in the least modified by the conditions to which they were subjected.

The State Hospital Bulletin is the title of a new quarterly journal issued by the lunacy commission of this State. It is intended to be the organ of the State hospitals for the insane and it will publish the clinical and pathological work of these institutions. The pathological department will be under the direction of Dr. Ira Van Gieson, who has recently been appointed chief of the State Laboratory. The first issue contains a number of articles upon subjects of brain tumor, typhoid fever, and thyroid feeding in insanity. The volume as a whole is a very creditable one.

Diphtheria is raging in some of the towns of Gloucester County, N. J., along the Rancocas Creek. At Delanco the public school has been closed and the churches have discontinued services. The schools at Riverside also have been closed.

Obituary Notes.—DR. LEOLF REFSE, a prominent physician of Stockton, N. J., died on February 17th, from pulmonary tuberculosis. He was sixty-two years of age, and was at one time a practising physician in Chester County, Pa.—DR. R. L. SIBBETT, an eminent physician of Carlisle, Pa., and a member of the State Board of Charities, was stricken with paralysis on February 18th.—DR. CURTIS J. NICI, a resident of Philadelphia, died on February 15th, at Winter Park, Fla., in consequence of paralysis. He was in his sixty-second year, and was graduated from Jefferson Medical College in 1854. For two years he lived and practised his profession in the State of Illinois, but subsequently he returned to Philadelphia, where he continued in active practice until three years ago.—

DR. SMITH ELY, for many years a leading physician and surgeon in Newburgh, died February 27th, of heart disease, aged sixty-eight years. He studied medicine in New York, London, and Paris, and graduated from the Vermont Medical College. For a time he was one of the resident physicians at the Emigrants' Hospital, Ward's Island.—DR. LAUGHTON MCFARLANE, professor of surgery at the Toronto University, died February 29th of septic infection, contracted while amputating the toes of a patient at the General Hospital a week ago. He was fifty-four years old.—DR. EDWARD EVERITT, of Newark, N. J., died February 27th, aged thirty-eight years, of malignant diphtheria, supposed to have been contracted in attending two children. He felt a soreness in his throat on Sunday. When it became worse he regarded it as quinsy and treated it accordingly. He attended to his practice until within a day of his death. Then he called in Drs. Beggs and Moffett. They found that he had an extremely dangerous case of diphtheria, made worse by neglect. Dr. Everitt was a bachelor.—DR. NELSON FANNING died at his home at Catskill on February 28th. He was born at Gilboa, Schoharie County, in 1808, and has been a practising physician in this State for sixty-six years and was surgeon of the Eleventh Corps of the Army of the Potomac during the war. He was a prominent member of the Medical Society of the State of New York. He leaves two sons and two daughters.—DR. DAVID W. MAULL, a prominent physician of Wilmington, Del., died on February 23d, after a short illness. He was sixty-five years of age, and was a son of Dr. George W. Maull. He was graduated from Jefferson Medical College in 1853, and later served as surgeon on a steamer plying between Liverpool and Philadelphia. When the war broke out Dr. Maull entered the Delaware volunteers and became captain. When his term expired he re-enlisted and became a surgeon. He was in nearly all the battles of the Army of the Potomac. Dr. Maull was surgeon-in-chief of the Second Division of the Third Army Corps. After the war he settled in Wilmington, where he lived until his death. For six years he was city vaccine physician.—DR. OWEN JONES WISTER, a well-known practitioner and a member of a distinguished family, died at his home on the Old York Road, near Mill Street, Branchtown, on February 24th, at the age of seventy-one years. He was graduated from the University of Pennsylvania in the year 1847, and a year later entered the U. S. Navy as assistant surgeon, serving for four years. He was a member of numerous scientific bodies, and was a warm anti-vivisectionist. His funeral was attended by many prominent men, among the honorary pall bearers being Judge Biddle and Drs. S. Weir Mitchell and J. M. Da Costa.—DR. JAMES W. ELLIOT, of New York, died on February 28th, aged seventy-two years. He was born in England, graduated from the New York College of Physicians and Surgeons in 1850, and had practised in this city most of the time since. He was connected with the Cunard steamship line and the Eighth Avenue street-car line, and for many years he was an active worker in the Episcopal Church.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

OBSTETRICAL SOCIETY'S ANNUAL MEETING—PRESIDENT'S ADDRESS—THE MIDWIVES QUESTION, THE SOCIETY, AND THE PRIMROSE LEAGUE—MEDICAL CERTIFICATES AND THE SCHOOL BOARD—EXHIBITS AT THE MEDICAL SOCIETY MEETING—SMALL-POX—THE QUEEN'S SPEECH—MR. COWELL—THE LATE MR. COLLUM—ANTHRAX.

LONDON, February 14, 1896.

THE annual meeting of the Obstetrical Society was held last week, when Dr. Champneys as president delivered an address. He reviewed the communications that had taken place between the society and the General Medical Council in terms which can scarcely be described as examples of good taste. He taunted the opponents of the society with having "twisted the tail of the council," and plumed himself that the result had been a victory for the society, which had now managed to get the formal *imprimatur* of the council for its examinations, which are accordingly on a firmer footing than before. Dr. Champneys proceeded to denounce a spirit of trade unionism which he considered discreditable to an honorable profession, and boasted that the certificates issued last year were more numerous than ever, being no less than four hundred and sixty-seven. There is, however, another side to the question; it is all very well for Dr. Champneys and other consultants to endeavor to run midwives in competition with medical practitioners, but, as the latter already find great difficulty in earning a livelihood, they fail to regard these consulting obstetricians as friends. It is all very well for consultants who do not wish to attend natural labor except for unnatural fees to despise those who are glad to earn honest guineas, and to object to their practice being undermined by the intrusion of women with three months' teaching, who flaunt the society's diploma in their faces. It is all very well, too, to pretend to be shocked at the spirit of trade unionism, but when professional union is complete among general practitioners they may refuse to call in consultants who have assisted in ruining their practice. The same thing applies to those who are so urgent in their desire for the registration of midwives, some of whom have actually appealed to the Primrose League to assist them in their agitation. The local secretaries of this political league have been favored with communications from Sir John Williams and Dr. Cullingworth advocating this scheme. The opportunity of advertising themselves to these Primrose dames may not prove so profitable as they imagine, considering that three-fourths of the profession are opposed to the scheme, and that the time may not be far off when the Union of General Practitioners will be driven to ostracize those who advocate the legalizing of a new competition by ignorant women, and the affected horror of trade unionism by a few consultants will prove the most powerful incentive to such union.

The resolutions carried last week at the meeting of medical men to consider the action of the school board were marked by courtesy and decision and, it is to be hoped, will lead the board to annul its action. Certificates are given to children as well as to candidates for the office of teacher without any remuneration, and then the school board has ventured to subject such certificates to revision. It looks almost as if this were an object lesson on the evil of our gratuitous system, which, as remarked by Dr. Glover, has pretty well demoralized the profession. If the certificates are to be ignored they would better be

refused, as Dr. Ward Cousins said, and as Mr. Cowell declared he had already declined to give them. Other well-known speakers expressed their disapproval of the school board's action, and there seems no reasonable excuse for the board persisting in a course which is most offensive to the profession.

On Monday there was an exhibition of clinical cases at the Medical Society meeting, among which were dislocation of the hip into the obturator foramen treated by excision of the head of the femur, and also a case of unreduced dislocation into the same foramen which it was proposed to treat similarly, though a question arose whether in this case there was not a fracture. Then there was a case of laminectomy for paralysis due to cervical caries in a girl aged thirteen. The operation was successful.

Two cases of sinus over the sacrum and coccyx were also shown, which had healed rapidly after being laid open, scraped, packed with dry wool, and duly fomented. A case of colotomy followed by subsequent enterectomy for cancer of the upper rectum, in a woman aged fifty-three, was also successful, the patient having continued well since August. A girl aged seven was also shown, in whom the interior of the left os calcis had been scraped away, as well as the outer and part of the lower walls, the cavity of which was tightly packed with decalcified bone chips and iodoform, and the skin sutured. The wound healed by first intention, and Mr. Waterhouse said he had been also successful with seven other cases and considered that the chips acted as temporary aseptic scaffolding and were replaced by new bone.

Mr. George Cowell has retired from the surgency of the Westminster Hospital and the Royal Westminster Ophthalmic Hospital, which he has served for twenty-seven and twenty-five years respectively. He has been appointed consulting surgeon to both.

Small-pox has continued stationary in London, but outbreaks have continued to occur in the provinces.

In the Queen's speech at the opening of Parliament we are promised a new public health bill for Scotland, a water bill for London, and a bill to check the importation of destitute aliens.

Mr. A. T. Collum, assistant surgeon to Charing Cross Hospital, died on Wednesday afternoon of septicæmia.

Five cases of anthrax have been admitted to Guy's Hospital, all contracted at the same factory by handling goat skins. They have been treated by excision of the primary lesions.

OUR PARIS LETTER.

(From our Special Correspondent.)

PARIS HOSPITALS AS NESTS OF TUBERCULOSIS—MICROBE OF HOSPITAL GANGRENE—MICROBE OF HEMORRHAGE.

PARIS, February 15, 1896.

MICROBES! Everywhere! Even the wards of the Paris hospitals, supposed to be the cleanest, the best disinfected, and the best swept in the world, are now incriminated as the origin of cases of tuberculosis, quite recently contracted within their walls. These cases all occurred in perfectly healthy, even robust, individuals who were entirely free from tuberculosis upon entering the hospital, and none of whose ancestors on either side had ever been known to have tuberculous taint of any kind. They were reported by Professor Jaccoud in his service at the Hôpital de la Pitié, and his report of them has given rise to sharp discussions not only at the Academy of Medicine but also among the profession at large. When we say that the Paris hospitals are the best swept in the world we at once explain all, for in their dusts the

death-dealing bacillus floats and is breathed by the unsuspecting patient or convalescent, both of whom are in perfect health so far as tuberculosis is concerned. Unfortunately tuberculous patients are put into the same wards with others, with but a very few feet separating their beds, and when we remember Villemin's experiment of causing dogs to breathe dust obtained from dried tuberculous excretions, and how those dogs all became invariably tuberculous, it is not necessary to look farther for an explanation of these startling facts. And yet there are men of eminence who still deny the contagiousness of tuberculosis—a disease that is highly contagious. Although it is impossible in every case to give the mathematical proof of contagion, because patients who have been in contact with others having tuberculosis leave the wards before the disease has had time to develop, we have been able to trace Professor Jaccoud's cases from the source of contagion to the autopsy. The mortality rate from tubercular disease among nurses and hospital attendants is far higher than is ever made known. The same mortality is also very great among students. Yet nothing seems to be done to prevent contagion. Professor Terrier informs us that at the Hôpital Bichat, the room in which the mattresses are made is situated under a ward filled with patients. These mattresses are so little disinfected that he has found lice in them. There are spittoons in the hospitals, but no one spits into them. Moreover, they do not disinfect the wards. At the Bichat Hospital the medical wards have never been disinfected. When the employees become tuberculous they are refused every kind of disinfection. The wards are absolutely crowded. Courses of lectures on hospital hygiene are delivered at the École de Médecine, but at the hospital the contrary of hygiene is practised and everything that is necessary to spread tuberculosis is done. To remedy such a condition of things it is only necessary to have wards set apart for tuberculous patients exclusively. It is true that tuberculosis is contagious and that the dust of the hospitals contains the bacilli. If then the tuberculous patients are isolated, all danger from that source is averted. On the other hand, when a patient enters the hospital it is impossible to say whether he or she is tuberculous or not, for no disease is so difficult to detect at a certain period. It would be well if tuberculin could be injected, as is done with animals, but that is impracticable in general.

In this matter city practice differs entirely from that in the hospitals and physicians would not leave healthy children in the same room with a tuberculous brother or sister. In the hospitals, as already noted, tuberculous patients are placed in contact promiscuously with others. This it seems to us could more easily be avoided than in private practice.

Microbe of Hospital Gangrene.—A treatise on this subject has just been written by M. Chauvel, who considers hospital gangrene as a specific lesion, one peculiar to the human species. Its pathogenic microbe is a special bacillus, elongated, incolorable by the method of Gram and one that cannot be cultivated. It is found constantly in the pulp of the membrane covering wounds undergoing that complication. It often exists there exclusively. Its presence shown by the microscope will be a valuable aid in making a diagnosis and in judging of the degree of infection or amelioration of wounds affected by hospital gangrene.

Microbe of Hemorrhage.—Professor Charrin was the first to call attention to the fact that the hemorrhagic function was a property common to multiple bacteria. Hlava on the contrary asserts somewhat later that hemorrhages are due to a special bacillus, which associates itself with the different

morbid agents each time that an extravasation of blood occurs. This opinion is endorsed to-day only partially—the hemorrhagic function being common to bacilli already well known, such as the coli bacillus and the streptococci.

A PLEA FOR THE POTATO.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: If the potato had tongues, instead of eyes, it would long ago have raised a cry of protest against the outrages that cookery perpetrates in its name, but with long suffering that is commendable, even in a potato, all has been borne in silence; but now that it is being so strongly condemned by some writers the climax seems to be reached. Insult is added to injury, and it behooves some one to champion its cause.

No less an authority than Edward Smith in his work on "Foods" (International Scientific Series) says: "Of all kinds of fresh vegetables grown in temperate climates, none is so valuable as the potato (*solanum tuberosum*), when we have regard to its agreeable flavor and nutritive and medicinal qualities, so that it is eaten daily by almost every family, and with the addition of buttermilk or skim milk was, until recently, nearly the sole support of a whole nation." So much for the potato fresh from Nature's laboratory. When the cook is done with it, however, it may be a very different thing—but that is the fault of the cook and not of the potato—and this seems to be the root of the trouble (as well as the trouble of the root). Let us consider the potato *per se*, unencumbered by undesirable cookery, and we have nothing at which to be alarmed. The fact that it contains very little nitrogen is no reason to condemn it, for we are prone to have a dietary of too concentrated foods, and the system demands bulk for the proper intestinal action as well as for nourishment. Here the potato is most useful. It would be unfit for the sole diet, as such large quantities would be required to satisfy at all the demands of the body, which even then would not be perfectly nourished; but combined with nitrogenous substances it is a valuable food when properly cooked. It contains less starch than rice, peas, lentils, etc., so is less harmful than they where starch is objectionable in the dietary. Again, it has less woody fibre than the other underground vegetables, which is, of course, in its favor from the digestive point of view.

It seems like a sweeping injustice to ascribe American dyspepsia to the humble potato. It certainly has not made a nation of dyspeptics of the Irish—and they have given it a severe test—and it seems unlikely that it would make any race distinction and discriminate against us. Plainly American dyspepsia must seek for some other cause than the potato *per se*.

When fried, warmed over, or transformed into Saratoga chips, croquettes, or any of the many indigestible things that modern cookery has devised, it is objectionable, but what food would not be? Even when baked or boiled it is also objectionable unless the cooking is properly done, and the fact that it so seldom is properly done is doubtless the cause of much that is said against it; but do let us lay the blame where it belongs and remedy the evil by teaching our cooks how to prepare it properly, not by eliminating it entirely or even partially from our tables.

Shorn of details, an incident that several years ago occurred in the writer's family may be cited in this matter. The baby girl of the household, when a little over a year old, began to refuse her food. In spite of tonics and a change to country air, this state continued. Many different foods were tried and all that eminent medical skill could do or suggest was

unavailing. Concentrated nourishment and stimulants kept the spark of life flickering, but even these were failing. Her temperature was below normal and death's finger seemed already laid upon the wasted baby frame, and death was coming through starvation—starvation in the midst of all the foods that modern science had given us. Finally, with death as the alternative, the physician said: "Take her to the table, and if there is anything that she will eat give it to her." And she did eat a little mashed potato!—the first food that she had taken willingly for a month. This was the turning-point. The convalescence was very slow but it was sure, and all through it potatoes were her only food, except such small quantities of other foods as could be mixed with them without affecting their flavor perceptibly. Gradually she began to take a little milk and other things, and health returned permanently.

After such an experience a word in defence of our humble tuber is only an expression of just gratitude for benefits received.

R. M. J.

NEWSPAPER DOCTORS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: For the last two months I have been on a visit to this city from the "wild and woolly" West. I have seen and heard some very strange things in this great metropolis, but I have borne everything in silence and "boiled within" until a few days ago, when your daily newspapers began to fill their columns with purely medical topics concerning the Roentgen rays. Is it not about time that some strictly medical publication raised a protest against the commercial and unethical methods of some of our brother physicians to gain notoriety and thereby more patients? The most flagrant example is the young physician who sketched a very rudimentary brain on his photograph and blamed it all on the cathode rays; a more incorrect picture of the human brain has never been seen even in some of our Western patent-medicine advertisements. Of course the experimenter was careful that his address graced the newspaper articles and he very ingenuously objected to showing or explaining his complicated apparatus, fearing that some inexperienced imitator might lose his life by endeavoring to reproduce his results. With the assistance of a medical friend I readily ascertained that this noted hypnotist and cathode photographer was a few years ago a nurse in Mt. Sinai Hospital. He then entered the New York University Medical College, but was unable to pass his final examinations and received his degree from an institution which grants medical degrees after three months' residence.

Is it any wonder that the practice of medicine in the hands of such men has fallen to mere dollars and cheap advertising, thereby casting odium on every honest physician in the city?

An evening newspaper has a medical column in which prescriptions and medical treatment are given to suffering readers. A physician paid a certain weekly stipend signs this medical column, and many druggists in this city put up the prescriptions. How can any conscientious medical man prescribe for a patient who diagnoses his own case, whom he has never seen, of whom he knows no history, and worse than all, how can you reputable physicians in New York allow such a thing to go on? I realize that we Westerners are uncouth and uncivilized, but we are not "tenderfeet" and we certainly would not allow such business out in Colorado; our remedy would be radical but certain; one dose of tar and feathers or riding on a rail would be sure to stop all further nonsense.

Just think of it! Here we have a member of the County Medical Society, a physician on the Board of Health, allowed to prescribe in the daily papers, without one word of protest from the County Society or from the medical journals. Is it any wonder that your hospital boards and charity commissions have no physicians among their members? The majority of solid business men certainly can have no regard for a profession that allows its members a free and unlimited sway to advertise by means of reading-matter in the newspapers and to make use of any pretext for getting hold of a reporter's ear. This was intended to be only a short note but I fear it has grown into rather a long sermon; but my blood is hot and in my natural, breezy Western way I have tried to make things clear, and with an innate dislike for the untrue and the unreal, I want to raise my voice in indignant protest against the dark and devious ways of the fakir in medicine.

GEORGE A. WILSON, M.D.

NEW YORK, February 17, 1896.

DR. EDSON'S ASEPTOLIN—A CRITICISM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It is quite probable that we are on the eve of discovering or inventing a cure for tuberculosis which shall be entirely rational and at least as successful as the antitoxin treatment of diphtheria. For this reason the reports of all original investigation into the therapeutics of tuberculosis are eagerly read and closely criticised.

Dr. Cyrus Edson's article in the MEDICAL RECORD for February 8th will undoubtedly excite a good deal of interest and bring forth some unfavorable criticism.

In the first place Dr. Edson has not allowed a sufficiently long period of time to elapse to justify his pronouncing a single case cured. In the history of the first case he gives, treatment was begun on the 3d of September last. I am aware that he discusses conditions which might make the cure apparent, while as a matter of fact the disease is only in a quiescent state; but in summing up his two hundred and sixteen cases he says that "twenty-three have been discharged cured." Certainly two and perhaps five years should elapse after every vestige of the disease has disappeared before a verdict can be pronounced.

In the beginning of his article the doctor has drawn some conclusions which are unwarranted by the evidence. Speaking of the production of phenol within a body suffering from bacterial invasion, he says: "The increased secretion of phenol by the system during the disease is, in fact, one of nature's many devices to cure the underlying condition, to destroy the germ infection." Now, there is not one scrap of evidence to show that a sufficient quantity of phenol has been produced within a diseased body to destroy the parasites producing the disease. The implication here is very strong that a germ disease ceases when the body has produced sufficient phenol to destroy the germ or inhibit its growth. Buchner, however, found (Gunther's "Bakteriologie," S. 185) that during the course of a self-limited bacterial disease a certain albuminous body is produced which destroys the disease germ. He found that this substance was in solution in the blood serum, that it could be removed by dialysis in the presence of water, and that it destroyed the same bacterium that produced the disease in an artificial culture medium. Indeed, the efficacy of the serum therapy depends entirely upon the production of these albuminous substances. It is well known, too, that an attack of a self-limited bacterial disease confers immunity upon the subject attacked. Sometimes this immunity is perpetual and sometimes it lasts for only a few months. If the phenol were

the agent effecting the cure, it would produce no immunity, for it is not cumulative; on the other hand, it is very diffusible and is eliminated within twenty-four hours (Bartholow's "Therapeutics").

"This reasoning," says Dr. Edson, "naturally led me to think that phenol was selected by nature for the cure of some, if not all, of the so-called germ diseases. Of course the conclusion was obvious, but the corollary of that conclusion, which assumed a great importance in my mind, was this: If nature herself provides phenol during disease, then it cannot be possible that she will not tolerate the administration of the agent in effective dosage." (!) These are certainly amazing statements to be made with that deliberation which should characterize the language of a thoughtful scientific investigator. It is difficult to conceive of reasoning more inane or childish than this. Sugar is a useful article produced by the diseased condition known as diabetes mellitus; but that does not signify even the remote possibility of sugar being a useful agent in the treatment of diabetes. The amount of uric acid excreted is increased in all bacterial diseases attended by an elevation of the temperature, but this fact certainly has no therapeutic significance.

Furthermore, it is as firmly established as any fact can be established by experiment that the internal administration of no germicide is efficient in the cure of disease unless it can be given in quantity sufficient to make a solution of the circulating fluids of the body strong enough to prevent the growth of or to destroy the parasite outside of the body. The fluid used by Dr. Edson, injected hypodermatically, contains not quite $2\frac{3}{4}$ per cent. of phenol. Of this solution he administers from 70 to 120 minims per day—from 1.91 gr. to 3.30 gr. Now, a man weighing, say, 130 pounds would have circulating fluids to the total amount of 10 pounds or 70,000 grains avoirdupois, estimating the fluids at one-thirteenth of the total weight of the body, which anatomists have found to be approximately correct. A maximum dose of Dr. Edson's "aseptolin" would therefore in such a case make a solution of his bodily fluids of a strength of 1 to 21,212—less than 1 to 20,000. But phenol is destructive of bacteria only in solutions of a strength of from 1 to 30 to 1 to 20, the weaker having little effect and the stronger a not very rapid effect upon cultures outside of the body. Clearly, then, Dr. Edson's remedy does not derive its value from the amount of phenol it contains. The doctor has not told us whether any phenol is produced in the body by the action of the tubercle bacilli. It is not likely, however, that an amount is produced sufficient to interfere with the conclusions drawn here.

As to the pilocarpine, no facts are at hand to warrant a conclusion regarding its value as a germicide. The amount given, .013 gr. to .021 gr., seems insufficient (estimating $\frac{1}{30}$ to $\frac{1}{20}$ gr. a therapeutic dose) to possess much power for good or for evil. Accepting the phagocytosis theory of Metschnikoff, and the statement that pilocarpine increases the number and activity of the two kinds of phagocytes, it may be a valuable agent in the treatment of tuberculosis; but, so far as the writer knows, sufficient evidence has not yet been adduced to warrant an unreserved acceptance of Metschnikoff's theory. If, therefore, Dr. Edson's remedy for tuberculosis should, after three or four or five years, prove to be as valuable as he would have us now believe that it is, its value will probably be found not to reside in either the insignificant amount of phenol or in the scarcely less insignificant amount of pilocarpine which it contains; but in a by-product of their combination or their combination with some other substance or substances in the fluids of the body.

A word more as to the doctor's criticism of creosote

as a remedy for tuberculosis. The writer believes that the doctor is not warranted in denominating this justly valued agent in the cure of tuberculosis a fad. Certainly the fact that it is irritating to the stomach is a serious objection to its use; but this objection is by no means fatal. The writer believes that he can collect indisputable evidence to prove that creosote has cured a great many cases of tuberculosis and that it possesses a greater value as a therapeutic agent in this disease than any other agent or, indeed, a combination of all the other agents thus far used for that purpose. It is impossible to read the reports of Sommerbrodt, Guttman, and Bourget without being convinced of this fact. The writer admits that his personal experience with the remedy has been very limited, but his success has been quite gratifying. And patients tolerate creosote in larger quantities than is generally supposed. If a properly prepared emulsion is made, relatively very large quantities of it may be taken without producing any gastric disturbance. A good deal of the indigestion produced by the exhibition of creosote does not come because of its local irritative action upon the gastric mucous membrane, but from neutralizing the peptic ferment of the gastric juice; for in cases in which the digestive powers were reinforced the amount of local disturbance was always much less. The writer has at the present time a patient under his care who has taken forty-five grains of creosote every day (except two or three) since November 25th (now February 17th). The patient at that time weighed a little less than 110 pounds. This amount is sufficient to saturate the fluids to a strength of 1 to 1,400. On two occasions he had slight gastric embarrassment, but only for a day each time. His improvement has been quite marvellous, he having gained as much as two pounds in weight in a single week while taking the creosote. We shall be obliged to stop the exhibition of the remedy for a while, because of the appearance of albumin in the urine.

JOHN MADDEN, M.D.

63, 64 SENTINEL BUILDING, MILWAUKEE, WIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I was fortunate enough, when working with Dr. Déclat in Paris in 1871, to learn from him his treatment of consumption by the hypodermatic injection of

Water (H ₂ O).....	98
Phenol (C ₆ H ₇ O).....	2
Total.....	100

In the *American Practitioner*, Louisville, Ky., March and April, 1887, pp. 225-230, 257-264, I published an article entitled "Pulmonary Tuberculosis: Its Antiseptic Treatment." An analysis of seventy-two cases treated by the carbolic (phenol) method, with the following results, was given:

- First stage of the disease, 31; all cured.
- Second stage of the disease, 35; $\frac{2}{3}$ recovered or improved.
- Third stage of the disease, 6; no improvement.

On my return from Paris on February 24th I read in the daily papers of aseptolin, Dr. Edson's cure for consumption. I found his article in your issue of February 8th, pp. 185-191.

His accepted analysis of aseptolin (Mott, chemist) is, p. 186:

Water (H ₂ O).....	97.2411
Phenol (C ₆ H ₇ O).....	2.7401
Pilocarpine-phenyl-hydroxide (C ₁₁ H ₁₆ N ₂ O ₂ OH.C ₆ H ₅)..	0.0183
Total.....	100

the composition of pilocarpine-phenyl-hydroxide deduced by calculation being as follows:

Pilocarpine ($C_{11}H_{16}N_2O_2$).....	53.92
Phenol (C_6H_5O).....	46.08

Total.....100

The process employed in making the phenic acid of Dr. Déclat has been imitated in producing aseptolin.

Aseptolin differs from phenic acid in containing a salt of pilocarpine, only one part of the alkaloid in 10,000 parts of water.

Of this alkaloid his daily injection contains from .5 mgm. to 1.67 mgm., while the accepted dose hypodermatically varies from 10 mgm. to 20 mgm., given not once but twice or thrice a day.

Even if the advisability of giving pilocarpine in phthisis be admitted, the small dose given and the statement of the discoverer of aseptolin that "phenol was selected by nature for the cure of some at least, if not all, of the so-called germ diseases" (p. 185) would seem to indicate that reliance could be placed upon phenol alone.

The claim is made that aseptolin, in the treatment of malaria, is "a specific and of even greater efficiency than quinine," p. 188.

Since 1871 I have successfully treated hundreds of cases of malarial fever by hypodermatic injections of a two-per-cent. solution of phenol, when both quinine and arsenic had failed.¹

My readers can judge of the newness of the discovery.

GHISLAIN DURANT, M.D., PH.D.

12 WEST FORTY-SIXTH STREET.

THE DAILY USE OF QUININE IN MALARIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the MEDICAL RECORD of February 15th, I noted a paragraph headed "The Prince and Malaria." In it mention was made of the daily use of quinine as a preventive in malarial districts in Africa. Permit me to state some inferences which are the result of eighteen months' experience as surgeon to l'État Indépendant du Congo. I was located at Sukungu, 300 miles inland from the west coast and ten miles south of the Congo River, in south latitude $5^{\circ} 01' 22''$, east longitude $14^{\circ} 16' 37''$.

My inference is that African malarial poison is much more virulent than the same poison in southern New England; the depression is greater whether the patient be foreigner or native; the temperature is higher and less susceptible to the influence of drugs; also, the so-called "remittent" fever is more common in proportion to the number of cases.

A second inference is that quinine is a preventive against the severer forms of African malarial poisoning. Among twenty foreigners—Americans 7, Englishmen 3, Swedes 2, Belgians 8—each one of whom took five grains daily, there was not a single case of the "remittent" type in fourteen months.

The "intermittents" seem always susceptible to quinine, if an anticipatory dose of from fifteen to twenty-five grains is exhibited from six to ten hours before the expected paroxysm. I always gave fifteen grains at the close of the sweating stage, both to anticipate a possible quotidian and as a tonic. Another experience was that quinine taken daily never prevented "intermittents," although it undoubtedly reduced every phase of their intensity.

Again, when quinine is given during a certain temperature that temperature is almost invariably maintained until the cinchonism has subsided. In my own case, with a temperature of 103.4° F., forty grains were exhibited in two doses within three hours. The same

temperature was maintained for twenty hours, but there was no remission.

While using quinine daily in five-grain doses I have repeatedly been drenched by rains and in rivers, have been forced to make a day's journey on foot and with an empty stomach, in fact subjected to all manner of exposure, without experiencing a severe malarial fever.

GEORGE H. JACKSON, M.D.

NEW HAVEN, CONN., February 25, 1896.

PERMANGANATE OF POTASSIUM IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I am under obligations to Dr. H. B. Garner and Dr. J. B. Leeson, of Traverse City, Mich., as their article upon this subject, published in the MEDICAL RECORD, February 22, 1896, is a confirmation of my article published in the MEDICAL RECORD July 13, 1895. I therefore take the liberty of claiming undeniable priority.

Since the publication of my article several physicians of New York and Brooklyn in treating tuberculosis have tried permanganate of potassium and salicylic acid with excellent success. As yet I have not heard of any failure.

My article gives also the reasons which induced me to make use of the remedies mentioned. These reasons were strengthened by a very interesting article by Dr. Prudden, published in the *New York Medical Journal* at about the same time as mine in the MEDICAL RECORD and stating the result of his researches, to the effect that the characteristic bacilli of tuberculosis are the outcome of this disease and that ptomaines cause it.

I would suggest the trial in other grave diseases of the remedies mentioned and especially in those of a septic nature. I should not wonder but it might have a good effect even in hydrophobia, meningitis cerebro-spinalis, and eclamptic convulsions.

Physicians are warned not to mix permanganate-of-potassium solutions with syrups or any other vegetable matter, as such a mixture will cause an explosion.

L. BARKAN, M.D.

122 FIRST PLACE, BROOKLYN.

"AMATEUR SURGERY."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Quite frequently at the public gatherings of medical men, when scientific and practical questions are advocated and discussed, one is treated to "facts," sentiments, and fancies that are not always relevant in so far as the subjects proper are concerned. Such facts, sentiments, and fancies being rather out of their proper place and time, they are not taken up for discussion or rebuttal. These facts, sentiments, and fancies dropped by the way are often amusing, sometimes instructive from a number of points of view, and sometimes shockingly disappointing, not so much in themselves as because of the sources from which they come. We can, all of us, with a little patience and less trouble become erudite; but only few, in spite of ever so much trouble and hard work and patience, can become inventive to good purpose, that is, to set free the potential abilities of the rest of our fellow-workers. With a little patience and a certain amount of well directed practice, coupled with more or less opportunity, a great many of us can acquire sufficient technical skill to allow us justly to assume the rights and privileges of surgeons, at least from a mechanical point of view. But a true surgeon is a good deal more than an expert manipulator of the scalpel,

¹ Vide New York Medical Journal, December 6, 1884, p. 644.

needles and threads, and asepticized dressings, although, alas, sometimes it is certainly not easy to see that surgeons are expert in anything else than technique. Old Hippocrates undoubtedly loved his profession, and if he was an egotist he was the right kind of an egotist. He was ready to call the physician (and in his day the physician was a surgeon too) Godlike only conditionally. And that condition was that he be a philosopher! And when may the physician, the surgeon, be called a philosopher? When he knows so much of what other people have opined as to be without an opinion of his own? No. It is when he has learned that effects have causes, that is, when he has become a reliable diagnostician. All else in medicine is mere mechanics and imagination.

The other evening at the Academy of Medicine a creditable surgeon, who is a good diagnostician and an ingenious technician, used a phrase which he meant to be severely condemnatory. He spoke of professional men doing "amateur surgery." Coming from a man of his standing the phrase lacks grace and is odd. An amateur is one who does what he likes as an avocation, just for the fun, or pleasure, or exhilaration, or edification there is in it, often as a relief from serious and laborious vocations. Who ever heard of a professional man cutting even a simple abscess for the fun of doing so? If our great men, or those who would be our censors, talk of "amateur surgery," why shouldn't they talk of amateur physicians? There is such a thing as reprehensible surgery as there is a shilly-shallying medicine; but surgeons, and especially those who are teachers and professors, ought not to accuse their *confrères* of being amateurs. A surgeon may be incompetent and an ignoramus, or criminally negligent; but just because surgery is his vocation, and especially because the professor helped to make surgery his profession, he cannot be looked down upon as an amateur. Surgical and medical amateurs are found in farmyards, among cowboys, on old-style sailing-vessels and coasting-steamers, but not in the ranks of the profession. Moreover, amateurs have done good and immortal work—it would take too long to write out a catalogue of their deeds. What many of us, who are willing to sit quietly and be instructed, wish is that our great men and censors would stick closely to the dictionary meanings which we ordinary mortals are obliged to talk by. Misunderstandings are unpleasant, and when our leaders lay themselves open to misunderstandings the rank and file are sure to go wrong. Let even our professors call a spade a spade. And now, Mr. Editor, if you have had the patience to bear with me thus far, be glad to have me end by allowing me to ask two questions: 1. Is there really such a bastard entity as a professional amateur? 2. Do our professors and our colleges admit his existence and take pride in having created him?

ADOLPH RUPP, M.D.

406 WEST THIRTY-FOURTH STREET,

Medical Men to Avoid.—The one who has acute exacerbations of insanity when exposed to any new fact. The one who is always successful with all his difficult operations. The one who always sees hundreds of cases of a rare disease. The one who can always match your case and improve on your treatment. The one who always finds you have omitted something in the examination of your case. The one who thinks he can talk well and is always ready to discuss any paper of the evening. The one who is always the first to do the new operation. The one who is in a chronic fear of being anticipated in his important discoveries. The one who in consultation feels it his conscientious duty to explain to the patient why he differs with the attending physician.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 24, 1896.

EDWARD D. FISHER, M.D., PRESIDENT, IN THE CHAIR.

Conservative Surgery upon the Uterus and Adnexa by the Vaginal Route.—DR. H. N. VINEBERG read a paper on this subject. Mention was made of the advance of our knowledge of pelvic diseases and of their treatment during the past ten years or more, and the later custom of removing the uterus where both tubes and ovaries had to be sacrificed. While this had resulted in relief in a greater number of cases than before, it must be admitted that even so radical a measure did not always free the patient from pelvic pain and other symptoms. This was due to the fact that some pelvic tissues must always remain, however radical the operation, and the disease process may have extended beyond the uterus and adnexa to them. Conservative surgery, therefore, was indicated, if by it the uterus and the whole or a part of the adnexa could be saved and the patient be relieved of her symptoms. He made a distinction between palliative and conservative pelvic surgery. The former implied letting out of pus through an opening in the vagina, a secondary operation being necessary sooner or later; it was a procedure, however, which was not to be despised, as it had saved many lives which would have been sacrificed had a more severe operation been performed in the first instance. Conservative pelvic surgery implied removal of diseased tissue short of complete sacrifice of adnexa and uterus.

Opening through the abdomen was always attended by immediate danger and also by the remote danger of stitch abscess and ventral hernia. These facts had prevented operation in the past until the disease had made considerable advance, usually preventing conservative work. Conservative pelvic surgery had received a strong impetus since the introduction of the vaginal method, which rendered it but little more dangerous than curettage of the uterus. It might justly be called prophylactic pelvic surgery.

Dr. Vineberg then read the histories of some cases illustrative of different types from a total number of about forty. The first was in a woman who had borne a child thirteen months before and was suffering from pelvic pain, etc., found to be due to gonorrhœal endometritis and urethritis. The latter was relieved, the endometritis was not. After some months of palliative treatment which did not effect a cure, and a pelvic tumor being felt, he made vaginal section, drew down the left ovary, and punctured some small cysts; he then returned it, drew down the other ovary and tube, and removed them because the ovary was disorganized and pus was present. The woman then made an uneventful recovery. Had he waited longer the other ovary would have become disorganized and might have demanded removal. Another case was that of a working-girl aged twenty-two, disabled from work by pelvic trouble; the uterus was displaced backward and the ovaries were prolapsed; pessary and non-operative treatment had failed. He made a longitudinal incision in the anterior vaginal wall, drew down the ovaries and tubes, punctured small cysts in the ovaries, and excised one of the larger cysts; he then returned the appendages, and made vaginal fixation of the backwardly displaced uterus, thus holding it forward. The patient was completely relieved. It was safe to predict that had she been allowed to go on a year or two longer both appendages would have become so

disorganized that a conservative operation would have been impossible. In another case a small subserous uterine fibroid was removed through vaginal incision. The work of A. Martin and other authors was quoted to show the value of conservative vaginal surgery.

Dr. Vineberg had found that the appendages could be easily drawn down through a longitudinal vaginal incision unless there were adhesions. In the latter case one should be prepared to make an abdominal opening if it became necessary after doing vaginal exploratory operation. The longitudinal incision was preferable to the transverse one because of freedom from endangering the ureters in front or the rectum behind. Then the anterior incision permitted of vaginal fixation of the uterus at the same sitting, for there was commonly posterior displacement of that organ. He preferred to open the abdomen in extrauterine pregnancy because the uterus in these cases was friable and easily injured in vaginal work. He laid special stress upon the necessity of keeping the patient abed, say, three weeks. Ten days was too soon to allow her up.

Dr. W. R. PRYOR thought the discussion turned on the choice between the abdominal and the vaginal operations. He could see no reason for changing his views of some years ago. As a basis for judgment the cases could be divided into those of disease of the pelvic organs with abdominal associations and those with only pelvic associations. In the former cœliotomy was indicated, in the latter usually vaginal incision. If, for instance, there were tubal disease associated with appendicitis, the abdominal operation was assuredly indicated. For exploratory purposes he would choose the vaginal route. In all localized suppurative pelvic troubles and in pyosalpinx without abdominal complications one should operate through the vagina. There were, however, cases of disease of the uterus and appendages in which an abdominal opening was indicated, as he had already suggested. In doing vaginal work he made the opening in the posterior cul-de-sac.

Dr. H. J. BOLDT, who had not heard the entire paper, said he understood by conservative pelvic surgery plastic work on the pelvic organs for the purpose of restoring their utility. He believed that this could be done on the ovaries and tubes through the abdomen better than through the vagina. If, on the other hand, one meant removal of pelvic disease, such as pyosalpinx or ectopic gestation, he held that it could be done as easily through the vagina and without certain risks attending abdominal section. All knew that if there were unilateral disease high up it was better to operate through the abdomen, and large fibromata could be removed better through an abdominal opening. In nulliparae the vaginal route would be attended by more bruising because of the small size of the vagina. It was not always necessary in suppurative disease to remove all of the diseased structure, yet the patient would recover sooner than if the abdominal route had been chosen. The uterus should be removed whenever it became necessary to remove the appendages of both sides.

Dr. EGBERT H. GRANDIN said all were agreed that conservatism in surgery is a desideratum. There was no doubt that for exploratory purposes the vaginal route should be selected whenever possible; if necessary the abdomen could be opened afterward; vaginal operation was always indicated for disease within the pelvis. If the disease was above the pelvic brim, aside from doing whatever was possible through the vagina the operation must be completed from above. If there were pus tubes, we should operate through the vagina. If adhesions existed above, or there were appendicitis, etc., we should make a supplementary abdominal incision. It need not be a

large one. It was simply a question of the locality of the disease, whether high or low. The primary shock, the pain, the length of convalescence, especially if forceps were used, were about as great in the vaginal as in the abdominal operation. The duration of the operation and the risk were a little less in the former when the disease was low in the pelvis.

Dr. E. B. CRAGIN thought that in a society like this doctors should be able to find a common ground of agreement, and on the present occasion all would probably admit that masses lying high should be attacked from above, masses lying low might be attacked from below or from above. The mode of operating could be called conservative under two conditions: 1, When chosen in preference to other modes of operating in order to conserve the patient's strength; 2, when chosen as a means of saving the pelvic organs. An example of the first was seen in puerperal infection, when it was better to open a collection of pus through the vagina and postpone a more radical operation, should it become necessary at all, because of the patient's present low state and one's inability to judge of the extent of the disease. In his opinion plastic work on the appendages, to save the child-bearing function, could better be done from above than from below, although he had had experience with both routes. In vaginal work he preferred posterior incision in most cases. Each case had to be decided on its own merits.

Dr. VINEBERG did not think one was capable of judging of vaginal plastic work on the appendages who had operated only through the posterior cul-de-sac.

Non-Nocere in Obstetrics.—Dr. JULIUS ROSENBERG opened his paper with the statement that one of the most noted papers read at the International Medical Congress at Rome was by Dr. A. Jacobi, entitled "Non-Nocere." In it he showed that not infrequently our desire to aid resulted in harm to our patients. This seemed to Dr. Rosenberg especially true in obstetrics. Labor was a physiological process, and ninety-five per cent. of all labors terminated normally when permitted to take their course. But not infrequently in our desire to do something we brought about a pathological condition. Puerperal fever stood foremost among diseases of childbirth artificially produced. While the mortality from this cause had been much decreased, it was far from *nil*. The author then quoted several authorities to show that the vaginal secretions and the bacteria normally present there were destructive to pathological bacteria, and practical experience had shown that puerperal sepsis developed more frequently when labor had been preceded by the vaginal douche than when this had been omitted. All that was required was disinfection of the external genitals and of the hands of the accoucheur. In his own practice he had had no cases of puerperal sepsis, but had seen a number in women attended by other physicians.

Time permitted him to touch upon but one other point illustrative of injurious consequences from interference. It related to fibroids complicating pregnancy. He had had six cases and not one had resulted in serious complications. All the mothers lived, five of the children lived. Such results were far superior to those where there had been operative interference, for the latter showed a maternal death rate of twenty-five per cent. He claimed, therefore, that with few exceptions myomatous tumors of the uterus had better be let alone until the commencement of labor.

Dr. SIMON BARUCH opened the discussion. He thought the question of antiseptic vaginal douches before labor had been settled against such interference

in a discussion before the academy many years ago. He believed the method now adopted by most advanced gynecologists in abortion was to empty the uterus completely, introduce a curette, and scrape out everything, claiming that this was the only safe way. His own experience was entirely opposed to such interference unless there were some signs of beginning sepsis or there were hemorrhage. He believed in letting the uterus alone, disinfecting as well as possible, and letting it expel its own contents.

DR. A. F. CURRIER thought the term meddlesome midwifery had outlived its usefulness. The value of antiseptic midwifery could not be questioned. In all cases of parturition the vagina and external genitals should be most carefully examined for lesions, and if any existed they should be closed. Gonorrhœa might exist, and one should always examine for suspicious discharges. If present, antiseptics could not be too efficient. Where sessile or otherwise obstructive fibroids existed in the uterus they were likely to cause abortion or interfere with labor, and operation was indicated. In other cases he agreed with the author, and would wait until labor commenced. He thought twenty-five per cent. was a high mortality rate for interference.

DR. GRANDIN endorsed the first part of the paper. He disagreed with Dr. Baruch as to non-interference in abortion. The uterus should be cleaned out thoroughly and antiseptics observed.

DR. R. W. MURRAY thought there was no more occasion for speaking of meddlesome midwifery than of meddlesome surgery or meddlesome medicine. It had been abundantly proven that asepsis could not be secured without antiseptics. Where harm had resulted from attempted antiseptics it was due to failure to carry out the principle. Necessarily there would be lesions and germs would be present also; if the latter were absorbed they would cause sepsis. He believed in cleaning them away. It was more important, however, to clean the external genitals. The napkin should be applied as soon as the child was born: expulsion of the placenta should not be waited for.

Resolutions on Bills before the Legislature.—On motion of DR. W. R. PRYOR the society adopted a resolution opposing Bill 727 before the legislature, entitled "An Act to Incorporate the Optical Society of the State of New York," etc. It would prohibit anybody besides opticians and physicians from prescribing glasses.

DR. LEWIS said it was especially objectionable because the examining power did not rest with the regents.

On motion of DR. GRANDIN the Stanchfield bill, tinkering with the law demanding preliminary education of medical students, was condemned.

On motion of DR. DANIEL LEWIS Assembly Bill 906, "An Act to Abolish the Office of Coroner," etc., was endorsed.

Cycling is said to greatly mitigate the symptoms of hay fever, relieving the eye irritation and keeping off the paroxysms of sneezing.

If one cannot ride with the mouth closed, the point of the tongue should be pressed against the upper front teeth, so as to break the force of the inspired air and make it warm.—MENDELSON.

Violent cycling tends to produce hypertrophy of the heart. Chafing of the labia may be in part prevented by tilting the saddle well backward. Virtue must be at a low ebb if such a cause can disintegrate it.—CARRINGTON.

The philosopher sees in the bicycle and the bloomer the inciters of the same diseases and the same immoralities as followed in the wake of the roller skate.—MARTIN.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, February 27, 1896.

WILLIAM R. PRYOR, M.D., CHAIRMAN.

The Indications for Alexander's Operation.—Dr. Paul F. Mundé was announced to read a paper on the indications for Alexander's operation, Dr. Edebohls on the indications for hysterorrhaphy, Dr. Vineberg on the indications for vaginal fixation, but each one intruded more or less on the province of the others.

DR. MUNDE said that since he performed his first Alexander operation, December 12, 1884, he had so frequently had occasion to express his views that he could add little more to-day. He had operated altogether ninety-seven times, and had become even more strongly convinced of the value of the method when resorted to in cases to which it was adapted. The indications were based on clearly drawn lines, as originally stated by Alexander: 1. In retroversion or retroflexion of long standing, in which pessaries either did not maintain the uterus in position or could not be worn because of pain. 2. In retroversion or retroflexion of long standing associated with relaxation of the uterine ligaments, pelvic floor, and vaginal wall, and consequent greater or less prolapse. 3. Prolapse of uterus with vagina, in which the Alexander operation was preceded by trachelorrhaphy or amputation of the cervix and followed by anterior and posterior colporrhaphy and perineorrhaphy. 4. Desire of the patient to be cured of her complaint, pessary and non-operative measures failing. 5. To keep the uterus in normally anterior and elevated position after adherent uterus and appendages had been loosened and restored to normal mobility. If the adhesions had been overcome without opening the cul-de-sac a pessary might answer.

Contraindications: 1. Adhesions of the uterus or appendages. This was an absolute and positive contraindication. 2. The possibility of retaining the uterus and appendages in normal position and making the patient perfectly comfortable with pessary, unless she insisted on a cure. 3. Prolapsus of the uterus and vagina of the third degree.

Dr. Mundé had had no deaths, and he felt sure that eighty-seven of the ninety-seven cases had remained permanently cured. He preferred the Alexander operation to ventral fixation because it was safer and left the uterus in normal, not abnormal, position. It did not interfere with gestation. As to vaginal fixation, it was being discarded in its birthplace, Germany.

Indications for Ventral Fixation of the Uterus.

—DR. GEORGE M. EDEBOHLS opened his paper with the remark that he thought the discussion of the different methods of lifting and retaining the uterus must be carried to a higher plane than one of mere technique. The uterus could be held forward by the different methods, but the chief point to consider in making a choice was what influence had the operation upon pregnancy and labor?

Regarding the influence on pregnancy of vaginal fixation of the uterus, Strassmann had observed the following disturbances: 1, Pain in the vaginal cicatrix; 2, abortions, twenty-five per cent.; 3, vesical pain and disturbances of micturition. The same author and others had reported the following disturbances during parturition: 1, Severe hemorrhage from rupture of vaginal cicatrix; 2, necessity for the Porro operation, death; 3, version rendered impossible, Cæsarean section done, death; 4, version rendered dangerous and difficult; 5, craniotomy. These difficulties had been due to abnormal fixation of the cervix below the pelvic brim, causing tendency to undue expan-

sion and thinning in the posterior uterine wall and firm fixation in the pelvis of the anterior wall, with hypertrophy of this portion of the uterus. The latter constituted the obstacle to delivery.

Milander had collected fifty-four cases of labor after ventral fixation of the uterus, with eleven difficult labors, two requiring Cæsarean section. The whole number of pregnancies was seventy-four; six terminated in abortion; ten had not yet been delivered; one had died. The latter was a case of Dr. Edebohls'; death was due to long-standing heart disease on the eve of confinement, and had nothing to do with the ventral fixation. Dr. Edebohls' own experience had been negative, he having performed ventral fixation seventy-three times. Eight of the women had become pregnant; one produced miscarriage upon herself at the second month; one died of heart disease, as just stated; a third died near term from sepsis due to retention of a dead fœtus, in no way connected with ventral fixation, as stated by Dr. Coe and Dr. Hanks, who had attended her: the remaining five of the eight cases were easily and safely delivered, one by forceps. Two anomalies had been reported by authors, namely, thickening of the uterine wall at the site of fixation and ballooning or compensatory dilatation of the posterior uterine wall.

In pregnancy, after shortening the round ligaments, a slight drawing pain, beginning with the eighth month of pregnancy and attributed, whether correctly or incorrectly, to traction on the ligaments, had been noticed in a few cases. Beyond this nothing had been observed.

The following conclusions were reached: 1. Vaginal fixation of the uterus does not come within the sphere of legitimate operations in women liable to future pregnancy. 2. In women liable to become pregnant the indications for ventral fixation should be limited to the utmost degree. 3. Ventral fixation is never indicated in uncomplicated retroversion. 4. Inability of the operator to perform shortening of the round ligaments may be an indication for ventral fixation, but not in the case of one claiming to be a specialist in gynecology. 5. Ventral fixation is indicated as an adjuvant in operations for prolapsus uteri et vaginae. 6. Ventral fixation is indicated as a conclusive step in all celiotomies in which the appendages are removed and the uterus left. 7. It may be indicated in aggravated sharp retroflexion, but he had seen no case of the kind which could not be relieved by the Alexander operation. 8. Ventral fixation is indicated under certain conditions in uterus unicornus.

Indications for Vaginal Fixation.—DR. HIRAM N. VINEBERG felt that his paper had been largely anticipated by the two previous readers. Nevertheless he took a different view of vaginal fixation. Like every new operation, vaginal fixation had at first been carried to the extreme and applied to cases to which it ought not to be applied. On the other hand, the reaction was going to the opposite extreme, which was also but a repetition of common experience. The percentage of disturbances at labor had not been greater than in ventral fixation, nine in fifty-two cases against eleven in fifty-four. Personally he had not met with disturbances of pregnancy or labor. In his first cases he did not open the peritoneum, but during the past six months he had entered the peritoneum through an anterior longitudinal vaginal incision, broken up adhesions, lifted the retroverted uterus, and fixed it by suture to the vagina. Out of twenty-nine cases operated upon in this manner there had been failure in none. He recognized but one contraindication, congenital retroversion with adhesion, in which it was doubtful if any operation would give good results.

In fifty-two cases of labor following vaginal fixation there had been difficulty in nine—one Porro, one Cæsarean section, two cervical incisions, five versions.

The difficulties arose chiefly from the circumstance that the fundus of the uterus was too firmly and extensively attached to the vaginal wall at the expense of the posterior uterine wall—what one might expect from Dührssen's method, or transverse incision in the anterior vaginal wall and firm fixation of the uterus by several sutures, the method which was practised in all but one of the nine cases. Dr. Vineberg's own experience and that of others had taught him that when certain points were observed in technique vaginal fixation would cause no disturbance during gestation or labor. It was indicated in all backward displacements of the uterus with or without adhesions, and with or without disease of the adnexa and in which surgical interference was demanded. It was particularly indicated when backward displacement was complicated by moderate prolapse of the uterus and vagina, and it found an undisputed field in women with very fat abdominal walls, and also, in opposition to ventral fixation, in women whose abdominal walls were very yielding. It could be done in nulliparae and even in virgins. The only contraindication was congenital retroversion with adhesions, and in such cases no method was successful.

DR. CHARLES P. NOBLE, of Philadelphia, said he had been anticipated by Dr. Edebohls. Two cases of his own of disturbance during parturition following ventral fixation had led him to ask for the experience of others. He was not yet ready to draw conclusions. In one of his cases the woman was confined by Dr. Norris, who found that the adhesion and thickening of the anterior wall of the uterus constituted a tumor obstructing the brim of the pelvis. The woman was delivered with great difficulty. A similar condition existed in the other case, to which Dr. Noble was called in consultation. They waited for labor pains, only with the result that the woman became septic. Delivery was impossible and he did Porro's operation, but the woman died.

In his opinion shortening the round ligaments was the proper operation if the uterus was at all movable. He had had best results from hysterorrhaphy in procidentia, supplemented by plastic operations. Most of these women had passed the child-bearing period. If he sacrificed the appendages he also removed the uterus. He did not feel disposed to try vaginal fixation.

DR. H. J. BOLDT thought no operation was comparable with shortening the round ligaments in posterior displacement with mobility. If we attempted to break up adhesions without incision we might be deceived, and then on doing the Alexander operation find it to fail. For posterior adherent displacement he would perform ventral fixation after breaking up the adhesions. Vaginal fixation might find a place in some cases of vaginal work. Its origin had been attributed to-night to Makenrodt, but Dr. Boldt held that Schucking first performed it and that recent work was but a revival.

Has Abandoned Alexander and Vaginal Fixation.

—DR. ILL, of Newark, thought the indications for operation were very plain. It should be done in all cases of retroflexion or retroversion when the uterus could not be kept in place by other means, or when the patient lived at a distance and could not be looked after while wearing a pessary. He had employed the three methods but had given up two of them—Alexander's operation and vaginal fixation. He had performed ventral fixation ninety times with good results. He could report three cases of pregnancy. They had terminated all right. Nothing had been said to-night of hernia following the Alexander operation. Dr. Coley had told him that he had operated on fifteen cases of hernia of this origin during a very brief period last winter. Dr. Ill had seen one case of hernia after ventral fixation.

DR. J. R. GOFFE had had experience with the three methods, and had welcomed vaginal fixation because it did away with the scars left by Alexander's method. His anatomical cures had been satisfactory, but he had had no experience with pregnancy following vaginal fixation. Disturbances had been reported abroad.

DR. E. B. CRAGIN had performed vaginal fixation fifteen times and had had a number of failures which might have been due to his technique, for only in the last three cases had he opened the peritoneum. He was about ready to give it up.

DR. A. P. DUDLEY thought there was only one condition in which the Alexander operation was indicated, namely, where the operator could assure himself that the uterus and appendages were perfectly movable and not diseased. This was hardly possible, and the operation, therefore, was one which was performed in the dark. He would prefer to do laparotomy and fix the uterus. In many cases the adhesions could be broken up with or without incision in the posterior cul-de-sac, and then on replacing the uterus and packing with gauze, in case of operation, a scar would form which would keep it in place without necessitating Alexander's operation or ventral fixation.

DR. H. L. COLLVER had but one fault to find. It was that the views of different speakers represented extremes. The different methods had certain objections. Many cases could be cured by massage, etc.

DR. BRETTAUER had never been favorably impressed with vaginal fixation. The only class of cases in which he thought of trying it was that in which Dr. Vineberg had advised against it, congenital retroflexion with adhesion.

DR. WHITE recited some experience.

DR. GALLANT had known patients to have worse dragging pain over the symphysis after than before the Alexander operation.

The chairman, DR. PRVOR, had done the operation which bore his name, fixing the corpus uteri to the curve of the bladder, in six cases before it became his custom to remove the uterus whenever he removed the appendages. He might resort to it again when women refused to have the uterus taken out with diseased adnexa.

The authors made some closing remarks.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 29, 1896:

	Cases.	Deaths.
Tuberculosis.....	125	112
Typhoid fever.....	7	5
Scarlet fever.....	116	16
Cerebro-spinal meningitis.....	2	3
Measles.....	523	21
Diphtheria.....	274	47
Small-pox.....	0	0

The Club Doctor.—Labor leaders may say what they will, the struggle for existence is keenest by far in the ranks of the professional class. Go lower, and you will rarely find the determined stand against contending odds which, for instance, the struggling doctor makes to earn a wretched living for himself and family. Few follow in Dickens' footsteps and write the quaint, pitiful romance of the shabby genteel, and yet there is infinite pathos in their sad efforts to keep the wolf from the door and their heads above the social slough into which Mrs. Grundy is longing to

plunge them. Club doctors are the slave class of the medical profession. For a fixed salary of at most £100 they are bound down to a slavery from which there is no respite day or night. The members of the club may number some eight or nine hundred, and some of these or their families are in constant need of medical attendance. Ever at their beck and call, summoned on the most trifling occasions, their doctor must tramp the streets at all times and in all weathers. His bell is always jangling, and he comes home only to set out again. Backward and forward he plods along the grimy streets of the wretched suburb where his practice lies, passing only from one scene of squalid sickness to another, and forced to use his poor remedies where rest and generous diet are alone needed. All the year round he keeps at his work with a desperate pathetic courage; he dares not leave it, for he is never without rivals ready to take his wretched clients from him, and he is far too poor to pay a substitute. No wonder that nature sometimes takes her revenge for an overworked body and exhausted brain, and that the club doctor finds his hands and head at fault and takes a life where he has saved thousands. If he were but an overworked signalman, a thousand voices would cry "Shame!" But he is only a doctor, and has no right to share the mortal weakness he must cure in others. Ruin and disgrace will be his portion, and the scathing comments of the public press on his "criminal carelessness" will block his way to gaining a living by his profession for the future.—*St. James Gazette.*

The Oldest Prescription.—A French medical paper prints what is believed to be the oldest known medical recipe. It is for a tonic for the hair and its date is 4000 B.C. It was prepared for an Egyptian queen, and required dogs' paws and asses' hoofs to be boiled with dates in oil. The modern hair restorer requires asses' heads.

Fractures of the Elbow Joint.—1. All fractures of the lower end of the humerus, once in position, are held in place if the forearm is kept acutely flexed. 2. Such flexion can be used without danger to the limb or undue distress to the patient. 3. The only force required being one of flexion, no rigid apparatus is needed, it being sufficient to strap the forearm to the arm. One of the strong points of this treatment, therefore, is its perfect simplicity. 4. The points to emphasize are: Be sure to replace fragments as flexion is made, taking great care that the internal condyle is as low as possible and the joint not widened by effusion between fragments. If the condyle is kept down, no gunstock deformity can occur. 5. In cases thus far treated the amount of motion gained has been slightly greater than after ordinary methods. The amount of deformity has been very much less.—SMITH.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

ATLAS OF TRAUMATIC FRACTURES AND LUXATIONS, WITH A BRIEF TREATISE. By H. Helferich, M.D., with one hundred and sixty-six illustrations after original drawings by Dr. Joseph Trumpp. 8vo, 230 pages, comprising 64 full page chromo-lithographic plates, with descriptive text. Muslin; price, \$3.50. Wm. Wood & Co. New York.

EPIDEMIC OPHTHALMIA; ITS SYMPTOMS, DIAGNOSIS, AND MANAGEMENT, WITH PAPERS UPON ALLIED SUBJECTS. By Sidney Stephenson, M.B. 8vo, 278 pages, illustrated. Macmillan & Co. New York. Price, \$3.00.

Original Lectures.

MIDDLETON-GOLDSMITH LECTURES—ON THE RELATIONSHIP BETWEEN INFLAM- MATION AND SUNDRY FORMS OF FI- BROSIS.

By J. GEORGE ADAMI, M.A., M.D. CAMB.,
PROFESSOR OF PATHOLOGY, M'GILL UNIVERSITY, MONTREAL.

MR. PRESIDENT AND GENTLEMEN: I cannot proceed to the delivery of these lectures without in the first place extolling the beneficence of him through whose regard for this society and generosity it has been made possible for you to institute this series of lectures—of him whom thus you are bound to keep in ever green remembrance. And in the second place I owe it not only to you but to myself to give utterance to my very sincere gratitude for the honor done me in inviting me to attempt to fill a position in which already the great pathologists of this continent have one after the other added new leaves to their laurels. For myself I cannot hope to vie with my illustrious predecessors. I can but exceed them in appreciation of the honor done to me, and through me to the city and university of my adoption. I feel acutely your kindness in thus inviting to deliver these lectures one who is a stranger among you, one who as yet can scarce feel himself other than a stranger to this continent. For my university it does not need that I should be specially empowered to announce to you how, striving toward higher things, that university appreciates and is encouraged by every act of recognition from the larger world.

It might, perhaps, sir, be expected by that larger world that I should here make due and telling reference to my presence among you at the present epoch. I am inclined to think that when the universality of science and our common brotherhood in it are so obvious to all of us, and the insistence thereupon is to us so much of a truism, it were almost an insult to your intelligence and good will did I say anything, however much I may personally appreciate your kind invitation at this especial juncture. The most I dare venture is to express the fervent wish that the same fellowship may bind together the nations which now unites all those striving after good works in all branches of science.

Throughout the days of this generation, and to an increasing extent in these latter days, there has been and there continues to be a lively discussion as to what is and what is not to be included in the scope of inflammation. And as of late among a narrow sect of surgeons or surgical pathologists there has been manifest the revival of what, were I a theologian, I should denominate a (not unqualified) heresy, but what, as a pathologist, I prefer to describe as, in my opinion, a serious misconception, I have thought it well, not only from the interest excited by the subject in our body but also from the recrudescence of this misconception, to select as the subject of these lectures this matter of

inflammation and the relationship existing between it and fibrosis or fibrous hyperplasia in its various forms.

Even at the best this is a subject involved in difficulties. How involved I did not wholly realize until some months ago I was called upon by my friend, Prof. Clifford Allbutt, of Cambridge, England, to discuss the matter succinctly in the course of an article upon the "Pathology of Inflammation in General," and was forced to face the matter straightly. As I doubt not, most here present have found it is one thing to have general opinions, another to place them in logical sequence upon paper. When I came to attempt the latter, and again to consult the accounts given in the leading articles and text-books, I discovered not only the inconsequential nature of many of my previous views but also that most of what had already been written read like the writing of scribes rather than of those having authority; and after having written the article or section of an article already referred to I cannot but feel that what is there stated merits the same reproach, and since the manuscript left my hands the more I have deliberated the more dissatisfied have I felt over my own writing. I am glad to have this opportunity to revise and advance my views upon the subject, and even before the article in question is published to amend it and carry to a more logical conclusion the treatment of the principles upon which the article is based. I cannot hope to solve all or any of the problems that a study of this relationship between inflammation and fibrous-tissue growth opens up; at most, suggesting rather than dictating, I may possibly help others toward solution and may indicate the lines along which future research would seem to promise satisfactory results.

We are accustomed to employ the termination "itis" with the prefix "chronic" in almost if not quite every case in which there is replacement of the cell elements proper of a tissue by new fibrous-tissue growth. That is to say, we assume all these conditions to be of like origin, to be manifestations of chronic inflammation, or as the attempt at repair following upon acute inflammation.

Fibroid areas in the heart muscle are all grouped together under the convenient term of chronic interstitial myocarditis. Fibrosis of the valves of the heart with its sequelæ we speak of as chronic endocarditis. Arteriosclerosis is indifferently spoken of as chronic arteritis or endarteritis. Whatever the form of fibroid change occurring in the kidney, it comes under the heading of chronic interstitial nephritis. In the case of the liver it is true the conveniently non-committal name of cirrhosis is in English-speaking countries the term most usually employed to denote fibroid change, yet there are not wanting those who speak of chronic interstitial hepatitis.

I might similarly pass in order organ after organ of the body, with its chronic "-itis." Lax indeed is the employment of this common denomination of chronic inflammation, and its sole merit is its convenience in cloaking our ignorance of the exact causation of most of the conditions to which it is applied. In these lectures I wish to discuss how far and in what cases we are justified in the employment of the term, and to what extent the development of fibrous

¹ Delivered before the New York Pathological Society.

tissue in the more noble organs of the body is the result of inflammatory disturbance.

In such a discussion everything depends upon the definition of inflammation which is found acceptable, and the conclusions reached must stand or fall in the exact ratio in which the definition enunciated commends itself to other workers. Thus, first, it will be absolutely necessary for me to state clearly and distinctly what I understand by the term "inflammation."

Two courses, it seems to me, and only two are open to us with regard to our appreciation of the term. Either we can, with Thoma, agree that it is so unsatisfactory and that the discussions which have arisen as to its scope, or, more truly, as to the processes that are rightly to be included under the term, are so barren and profitless that we decide absolutely to expunge it from our vocabulary; or, on the other hand, we must determine to include in our idea of inflammation all processes having a like origin and tendency. There is no logical intermediate course unless it be to confine the term strictly to its primitive meaning and to determine that there can be inflammation only where there is "flaming," where there is redness and heat. No one is prepared nowadays to take this course, for this necessitates physiological active congestion of a superficial organ being considered as inflammatory. Nor again are there many who, wedded to tradition and cardinally virtuous, with Celsus only see inflammation when rubor, calor, dolor, and tumor are present. For these cannot deny that identical processes may occur when one or two or more of these cardinal symptoms are wanting. Thus, nowadays, those who would define inflammation etymologically are non-existent, while the partisans of tradition are "minished and brought low," forming a small and an impossible remnant. Hence, to return to my previous statement, there are but two logical courses open to us. Can we accept the first alternative and banish the idea of inflammation? I trow not—the suggestion is too quixotic. It is not within the power of any workers in any one branch of our science, even if that branch be pathology, to expunge at will a term of universal employment, a term that has come down to us through the ages—a term which, however loosely and variously employed, does nevertheless for all cover a greater or less number of processes of common occurrence. We cannot in a widespread science suddenly create a "tabula rasa" and start anew. Just as were we to do away with the plutocracy and start equally endowed with worldly possessions, while in twenty years the old plutocratic families would perchance be non-existent as such, yet the amassing of money and possessions in the hands of a few would inevitably be manifested, so were we to banish "inflammation" from our vocabulary, in the same time or even less some other word would be surely in common employment to denote the same idea. It cannot be done, and as a consequence the adoption of the second alternative is our only practical course.

We have, that is to say, so to employ the term that it will embrace all processes having a like origin and like import. Thus, then, starting from the generally accepted basis that the process is in its essence local and that the prime cause of all inflammations is injury to the tissues, if we are prepared to admit that one common or allied train of results follows upon all injuries, we must as our provisional definition state that inflammation is the series of changes constituting the local reaction to injury.

This is to all intents and purposes Burdon-Sanderson's definition and is that which for the last quarter of a century has been most generally accepted. For myself I cordially accept it as a good working definition; but at the same time I cannot but consider that the researches made since 1880 have materially added

to our comprehension of the phenomena associated with the process and of their tendency, and permit us now to acknowledge the import as well as the origin of the process. Those researches have shown us that a very definite meaning is to be attached to the main vital processes which follow injury to a part. They have proved that the accumulation of leucocytes in the injured area is purposeful; that, whether by intra- or extra-cellular action, these cells are capable, up to a certain extent, of counteracting the irritant and of removing dead and effete material; they have satisfactorily proved that the inflammatory serum possesses both digestive and bactericidal powers greater than the serum of the circulating blood; they have demonstrated that the migration of the leucocytes into the inflammatory area is not a passive process, but an active one directly dependent upon the extent of the stimulus exerted upon these cells by chemical alterations in their environment; they have demonstrated that the amount of fluid exuded into any one region of the body varies *inter alia* directly according to the intensity of the irritant—the more intense the irritant the greater the extent to which it is diluted; while, further, the part played by the fixed cells in the immediate neighborhood is equally evident and equally purposeful, tending manifestly to result in the cutting off of the damaged area from the surrounding healthy tissue and again to replace the tissue that has undergone destruction. Hence I am impelled to define inflammation as the local attempt at repair of injury, or, more fully, inasmuch as there is a certain small class of cases in which all the symptoms of inflammation are present as a consequence of nervous disturbance wholly unassociated with previous local injury,¹ as the series of changes which constitute the local attempt at repair of actual or referred injury to a part. So that needless objections be not raised, let me emphasize the fact that I do not regard inflammation as synonymous with repair. Attempt at repair and repair are two very different things, and no more to be confounded than attempted suicide and suicide, or, not to approach too closely to a very delicate subject, than the Emperor William's recent telegram to the Boers and actual war between two considerable European nations.

This, then, is the definition I am inclined to lay down. Save in the small matter of the wording, I do not claim any originality, for others in different lands have given forth definitions embracing the same idea. Thus Neumann, in Germany, defines inflammation as "the series of local phenomena which are developed in consequence of primary lesions of the tissues and which tend to heal these lesions."² Bland Sutton, in England, is somewhat more restricted. "It is," says he, "the method by which an organism attempts to render inert noxious elements introduced from without or arising within it."³ I doubt whether Sutton is right in speaking of it as a method and to me the larger view appeals, not simply of counteraction against the irritant but also of attempt to bring about a return of the region toward a functional condition—but the definition contains the same recognition of the purposive nature of the process. And lastly, here at home, Councilman acknowledges the same. In his most lucid article in Dennis' "System of Surgery" he defines inflammation as "the sum of the phenomena

¹ The most striking example of this class is to be seen in the experiment which has been frequently repeated, among others by my colleague, Dr. James Stewart, of assuring a susceptible individual under hypnotic influence that the hand or other region has been burned or blistered, when within a very short period the part becomes reddened, swollen, and, it may be, the seat of marked serous effusion.

² Ziegler's "Beiträge," v., 1889, p. 347.

³ I here quote from Professor Senn, not having been able to discover the original passage.

which take place in the tissue as the effect of an injury. The object of these various phenomena is to overcome or to diminish the effects of the injury."

Whatever justice there might have been a few years ago in the objection that this view of inflammation is teleological, now, with the facts at our disposal, the objection is no longer valid. As well may the statement that the function of the heart is to propel the blood into the arteries be condemned as teleological, or objection be taken to the statement that digestion is the series of processes whereby matters received into the alimentary tract tend to be converted to the uses of the tissues of the body. We are ready enough to admit the deductions drawn from physiological experiments; we must equally accept the results of experimental pathology.

But the definition here enunciated is altogether too broad for many to accept, and ever since Hüter propounded the view that the term inflammation ought to be restricted to those conditions in which there is infection by micro-organisms, with pus formation, there have not been wanting adherents of the narrower view. And as what is to follow must largely stand or fall according to the acceptance of the definition herein set forth, and inasmuch as this confounding of infection and pyogenesis with inflammation appears to be growing more and more popular upon this continent, I needs must for a short time discuss the propriety and soundness of the movement.

I do this, sir, with some hesitation, for I feel that I am reverting to very elementary pathology; nevertheless it is just because the matter is so elementary, so fundamental, so all-important for a right comprehension of all pathology, and because the distinction with which you have honored me affords an almost unique opportunity for calling attention to this matter, that I make bold to utilize this opportunity to urge a broad and logical consideration of the subject. Dr. Senn, professor of the principles of surgery in the Rush Medical College, Chicago, whose writings have obtained a wide circulation and whose influence in the North and West perhaps transcends that of any other surgeon, states in his "Principles of Surgery" that inflammation, in the widest and most comprehensive meaning of the word, should be made to embrace pathological conditions which are caused by the action of pathogenic microbes or their ptomaines upon the histological elements of the blood and fixed-tissue cells, and that "true inflammation is always caused by the presence of one or more kinds of pathogenic microbes," a statement which, it may be added in parenthesis, does not prevent him from employing figures from Hamilton and others to illustrate the stages of the process, although those figures represent the results obtained by the use of chemical and not bacterial irritants.

Dr. Roswell Park, professor of surgery in the University of Buffalo, in a straightforward address read before the American Surgical Association in May of last year² is inclined toward the same opinion, and, as he at the onset especially invites kindly criticism, I may say that his challenge has perhaps more than anything else led me to take up the subject here. He urges first the revolutionary thesis that the combination of the four cardinal symptoms should not be regarded as indicating inflammation. We should dismiss from our minds the associated idea, and should refer to the redness and heat as hyperamia, the swelling as exudation, the pain as the result of pressure. Only when these become developed or modified by the growth of micro-organisms in an injured area or by the action of their products should we venture to speak of inflammation. And the term should then

comprise not only the local but also the general effects produced by the growth of the micro-organism. In fact, the existence of these general effects (as, for example, the rise of bodily temperature associated with the appearance of a small furuncle upon the nose) is given as a distinction between what Dr. Park regards as true inflammation and the non-inflammatory reactions of the tissues to non-microbic lesions.

While epitomizing Dr. Roswell Park's argument, I believe that I have accurately stated his main contentions.

Let us see what is the logical outcome of this idea. First and foremost the frequent association of redness, swelling, heat, and pain which may result from microbic invasions of the body is not in itself to be regarded as symptomatic of inflammation. The association is common to microbic and many other lesions. Only the extension of this series of symptoms in special directions under the continued influence of bacterial irritation is to be considered as inflammatory; or, to carry this view to its logical conclusion, the surgeon must no longer depend upon the presence of cardinal symptoms; he must only call a region inflamed when he has either personally or through a bacteriologist determined the existence of bacteria therein. There is no attempt made by Dr. Roswell Park to limit inflammation to pyogenesis, and while this view of inflammation for surgical purposes, in the main, undoubtedly separates suppurative from other lesions, it is in the terms of this definition impossible to regard suppuration in itself as an inflammatory manifestation, simply because, as is well known, suppuration may be induced by caustics and severe chemical and physical irritants, apart from the action of bacteria. As above stated, the bacteriological is to become the sole sufficient test of inflammation. While it is true that the general adoption of this view would result in rendering it absolutely necessary that every general practitioner should continually practise himself in elementary bacteriology, or else should banish the term inflammation from his diagnostic vocabulary—a not undesirable consummation, it may be—I cannot but fear that the general practitioner will still continue to speak of the inflammation of scalded surfaces, of black eyes, and of fractured limbs; for he will still require some useful and generally accepted term to embrace the train of symptoms following upon every-day injuries. This attempt on the part of members of one branch of our profession to delimit our idea of inflammation largely for practical purposes must fail when put into practice.

Or let us examine the proposal from another side. "Without infection," says Dr. Roswell Park, "no genuine inflammation; with infection, inflammation and, what always goes with conflagration, more or less destruction. Congestion and exudation provoke little, ordinarily no constitutional symptoms; inflammation always does. . . . I would," he states later (after discussing hyperamia, congestion, and "cirrhotic" changes) "in an entirely distinct chapter and in an unmistakably separate way, take up the matter of inflammation—*i.e.*, infection." To all intents and purposes Dr. Roswell Park would substitute a word which, I think most will agree, has wisely been restricted to local disturbances for a word which has shown itself most useful as indicating the changes which may occur in the organism at large in consequence of microbic invasion. Up to the present time inflammation has been understood to indicate the local changes following upon an injury; fever and infection to indicate the more remote effects upon the organism at large. And I am forced to point out to Dr. Roswell Park that in "infection" he has a most useful word which will indicate everything that he wishes to include in his restricted idea of inflammation, and, that

¹ Dennis' "System," vol. i., 1895, p. 144.

² MEDICAL RECORD, New York, i., 1895, p. 705.

being so, there can be no valid reason why he should, with those "big, merciless hands" attributed by the late poet laureate to one of our surgical brethren, appropriate a word to which can be given a wider and at the same time a more exact use. The terms "wound infection," "local infection" and "general infection," and "infective inflammation," are in common and satisfactory employment and there can be little or no doubt as to their meaning. I beg Dr. Park to consider this before urging further the adoption of his proposals.

But while one is only too glad to have a word "infection" capable of covering the series of local and general effects induced by the presence and growth of micro-organisms within the body, its employment in nowise tells upon the fact that every change in the blood elements and tissues brought about by microbes and their products may be induced by irritants of another nature. While it is true that micro-organisms frequently lead to pus production and that suppurative inflammation is almost entirely induced by these agents, it is equally true, as was first clearly proved by Councilman, that sundry chemical substances can occasionally set up an identical process. And as Leber has shown, the purulent fluid produced by this latter means has definite powers of breaking up and digesting proteid matter; no clear distinction can be made between the septic and the aseptic pus save that the one is of microbic origin, the other not. A broad idea of inflammation to include all like processes throughout the higher animals must take cognizance of these facts.

Nor again, may I add, is it possible to distinguish one series of micro-organisms as essentially pyogenic. To attempt this is to draw a line between human and comparative pathology. While it is true that certain forms in man are peculiarly liable to induce abscess formation, those same forms by no means necessarily exhibit the same liability in other animals, and even in man they do not always lead to pus formation; in short, suppuration is the expression, not of the presence of certain specific microbes, but of a definite grade of intensity of irritation, or, in other words, it is a phenomenon representing a certain ratio between the virulence of the irritant and the resisting powers of the organism. Increase the virulence of a micro-organism or diminish the resisting power of the organism, and in members of the same species similarly treated we may have every grade of acute inflammation, from local hyperemia and slight diapedesis of leucocytes through local abscess formation, to spreading sero-purulent cellulitis and general septicemic infection. Much has been done experimentally to prove the truth of this statement, while the recent work in the laboratories of this continent upon cases of typhoid and gonorrhoea has abundantly shown how micro-organisms which in ordinary are not pyogenic can be the prime causes of abscess formation. Indeed it may be said with some truth that the main bacteriological work of the past year has been in the direction of confirming this statement and in demonstrating in case after case this liability on the part of bacteria ordinarily non-pyogenic to lead to abscess formation.

If this be so and if bacteria can thus be the cause of a series of reactive changes on the part of the tissues, advancing by imperceptible gradations from the simplest transient local inflammatory change up to the most profound generalized septicemic disturbance, and if again, as all must admit, they can induce either profound local destruction of tissues or well-marked local tissue overgrowth, then surely it is impossible to separate the lesions produced by micro-organisms from the parallel and identical series capable of being produced by other noxae.

I trust, therefore, that I have made it clear that we are compelled to range together the series of changes induced locally in the tissues as the result of injury under the common heading of inflammation, and this irrespective of the nature of the irritant.

For pathologists in general, for those studying not merely gross anatomical lesions but finer also, for those dealing with lesions of internal organs as well as with lesions having an outward manifestation, for those whose pathology and study of medicine is not confined to man and who strive to base their knowledge of disease and its processes upon a study of the same throughout the animal kingdom, no other course is open and practical.

Following this train of thought it becomes evident that we must regard as of inflammatory origin all those changes in the tissues which we can prove to result from direct injury to those tissues, whatever the nature of the irritant, and which we can regard as tending toward repair. We can separate the various degenerations of the tissues, for these form a well-defined series of changes from the inflammatory lesions proper; we may regard them as associated with but not inherent in the inflammatory change.

Of these local attempts at repair the most durable and, when the process has come to an end or when, being of moderate intensity, it has continued for some little period, the most evident is the formation of fibrous tissue. Now, in studying this formation and the broader subject of fibrosis¹ in general, the first point to be settled, one which will materially affect our whole comprehension and classification of the fibroses, is whether it is possible to distinguish between new connective-tissue formation which is directly the result of injury and that which is indirectly the result, and if we can determine this we can with greater freedom attack the question of the classification of the fibroses in general and can more surely state which of them are to be considered of inflammatory origin and constituting chronic "-itides," which non-inflammatory.

The first question is one of peculiar difficulty, and the problem presented for solution may perhaps be best approached by a consideration of two widely separated cases. A study of the various stages of the development of a tubercle demonstrates that in man and most mammals the first result of the lodgment and growth of the tubercle bacilli in the tissues is to stimulate tissue formation. Only at a later period, with continued action of the products of the germs and associated disturbed nutrition of the central area of the granuloma, does tissue destruction become manifest. There is perhaps no better demonstration than this, unless it be that afforded by lepra nodules, of injury leading directly to connective-tissue growth.

On the other hand, we may consider the processes which occur in the central nervous system following upon atrophy and destruction of ganglion cells or upon separation of axis-cylinder processes from their trophic nerve cells. The results can best be seen when the injury affects secondarily all the members of an ascending or descending tract, and they are to be summed up as consisting of degeneration of the fibres forming the tract with replacement by fibrous tissue. Here there has been no irritant circulating in the lymph bathing the fibres and leading directly by its action to their destruction. The degeneration and

¹ Here let me state that I have no liking for this mongrel term "fibrosis"; nevertheless, I know of none which can satisfactorily replace it. The terms "sclerosis" and "cirrhosis" indicate only the secondary consequences of fibroid overgrowth, and "fibrous hyperplasia" is a little clumsy, while "fibrosis" undoubtedly conveys clearly its meaning; and in its favor (although two blacks do not make one white) it may be urged that in common usage we have such other mongrel terms as "fibroma," "fibro-enchondroma," and so on.

atrophy has followed upon injury inflicted at a distance, an injury to another region of the body. If any irritant be present it is of intrinsic origin. All the same, we see that the atrophied fibres become replaced by connective tissue.

Are we to regard this "replacement" fibrosis as a form of chronic inflammation? Against so regarding it it can be argued that, as already stated, no specific irritant of external origin can be adduced as having acted upon the tract of degeneration, and that in case after case where the degeneration has been gradual none of the ordinary symptoms of inflammation are recognizable, neither the coarser conditions of hyperæmia and exudation nor those finer ones of determination of leucocytes (though this phenomenon is at times quite distinct), multiplication of capillaries and other microscopical evidences of removal of destroyed tissue, and active new growth. Almost imperceptibly the atrophied nerve fibres are replaced by connective tissue, and it may be that of all the accompaniments of ordinary inflammation the sole distinguishable is the "functio læsa."

But there is another aspect of the condition that we are forced to regard, and I may best approach this indirectly. What satisfactory distinction, it may with justice be asked, can be drawn between this more insidious replacement fibrosis and the grosser replacement occurring in the case of infarcts? In the latter the normal course of events is, that, infective agents being absent, the necrosed area becomes surrounded by a zone of hyperæmia, the dead tissue undergoes disintegration and absorption and is replaced by new fibrous tissue. In such a case, it is true, we can recognize the distended peripheral vessels, the invasion by leucocytes, the formation of new vessels, all the main microscopical and most of the macroscopical signs of inflammation. But, as in our previous example, no extrinsic agent has set up the disturbances. It is difficult, indeed impossible, to arrive at any other conclusion than that the products of necrosis act as the irritant and that they must be regarded as the cause of the inflammation and subsequent fibrous-tissue development. It is competent for us to assume the existence of a cryptic inflammation in the former case, and to hold that a like cause, namely, tissue necrosis, has led to a like effect, namely, fibrosis. And indeed if we adhere to the definition of inflammation that I have laid down, both of these cases of replacement fibrosis so obviously represent the local attempts at repair following upon injury to the tissues, that unless we further define what is meant by injury we are forced to regard them as equally of inflammatory origin.

We see thus that two different types of fibrous-tissue development, one hyperplastic, the other, as I have termed it, replacement, may be of inflammatory origin, and the more one examines into the subject the more difficult is it found to recognize inflammatory fibroses by their histological characters. While it is true that in certain cases we have histological evidence of progressive inflammation—the presence of newly formed vessels, of an increased number of extravascular leucocytes and small round cells, and it may be of a certain amount of exudation—in cases of the same nature at a later date all these signs may be wanting, and again, in other allied cases, from the very onset both microscopical and macroscopical indications of inflammation may be peculiarly rare. We cannot depend upon histological evidence alone. At the most we can classify the various forms according to the evidence in our possession as to their origin and tendencies.

PNEUMONIA AS A COMPLICATION OF DIPHTHERIA IN CHILDREN.¹

By HENRY W. BERG, M.D.,

ATTENDING PHYSICIAN TO THE WILLARD PARKER HOSPITAL, NEW YORK.

I HAVE been led to give interested attention to pneumonia as it occurs in diphtheria by the experience that in hospital practice by far the largest number of deaths from this disease are due to this complication. Thus the brilliant results otherwise obtained by the use of antitoxic serum in true diphtheria are materially diminished.

Dr. John W. Brannan, in an admirable statistical study of the results obtained in the Willard Parker Hospital from the serum treatment of diphtheria during nine months of 1895, found that out of one hundred and twenty-four deaths occurring during this period, sixty-six were due to broncho-pneumonia. To this must be added a case of pulmonary gangrene, which occurred during my service and which began as a broncho-pneumonia, so that more than fifty-four per cent. of the deaths from diphtheria were due to broncho-pneumonia. Sturges and Coupland found in autopsies on one hundred fatal cases of diphtheria that in twenty the lungs were unaffected, in eleven the lungs were congested, thirty-five showed pulmonary collapse and emphysema, in twenty the lesions of broncho-pneumonia were present, and in fourteen those of lobar pneumonia.

In private practice also this complication is primarily or secondarily the cause of death in a very large proportion of the fatal cases, and is also present in a considerable percentage of cases that recover in spite of the severity of the affection.

While I do not think it would be profitable to go into an exhaustive consideration of the pathology, symptomatology, etc., of a condition as well known as pneumonia, consideration of certain special features of the disease as a complication of diphtheria should prove of interest.

In order to avoid repetition it will be well to take up these data in the following order.

1. Etiological factors that enter into the occurrence of pneumonia in diphtheria.
2. Bacteriological and pathological data.
3. Clinical points of interest and data for prognosis.
4. Treatment—preventive and curative.

Etiological Factors.—Pneumonia may occur as a complication of any stage of diphtheria. I have recently seen a case of pneumonia in a child three years of age, complicating a diphtheritic tonsillitis. There was a history of sore throat for two days. On the other hand I have repeatedly seen in hospital practice a child convalescent from diphtheria, no more membrane being visible in the throat but Loeffler bacilli being still plentiful in cultures obtained from the throat, become affected by broncho-pneumonia, and this as late as the third week from the beginning of the disease.

A curious fact at the Willard Parker Hospital in this connection has been shown by Dr. Brannan, namely, that in 1895 the cases that died of broncho-pneumonia as a complication had had an average of 13.7 days of hospital care, while those that died in 1894 of this complication had had an average of two days of hospital care, which would seem to show that the antitoxin treatment had enabled even the most virulent of cases of diphtheria to resist the occurrence of this serious complication for a longer period than patients treated in 1894 by the old methods.

¹ Read before the N. Y. Academy of Medicine, March 5, 1896.

Sturges and Coupland found that where the lung became inflamed immediately after tracheotomy in cases of croup the complication was apt to be broncho-pneumonia, while lobar pneumonia is more apt to occur where the complication sets in a long time after the operation, when the child has practically recovered from the surgical lesion. Thus they report three fatal cases of lobar pneumonia in children occurring as a complication of tracheotomy for croup, one nineteen days and two twenty-four days after operation. The broncho-pneumonia which is one of the causes of death in some fatal cases of post diphtheritic paralysis is necessarily a very late sequel rather than a complication of diphtheria. But apart from these cases experience has taught that pneumonia may complicate a case of diphtheria as long as it remains diphtheria, that is, as long as there are Loeffler bacilli in the throat.

A variety of causative factors can be considered as determining the occurrence of pneumonias and other lesions of the lungs as complications of diphtheria.

First. In diphtheria of the larynx, the diphtheritic process can spread by direct continuity from above downward through the bronchi into the air cells, false membranes being found in the finest ramifications of the bronchi.

Second. Minute pieces of false membrane may be drawn by aspiration into the farthest ramifications of the bronchi, thus setting up a local bronchitis or diphtheritic broncho-pneumonia, there being no membrane in the trachea or intervening bronchi.

Third. In diphtheria of the larynx, where intubation has been practised, minute particles of liquid food may pass through the insufficiently protected tube into the trachea, and by aspiration into the bronchi, and thus start up a pneumonia called by the Germans "Schluckpneumonie." In tracheotomized cases minute foreign bodies may be drawn into the trachea and thus produce an inflammation of the deeper bronchi followed by a pneumonia; finally diphtheria of the larynx and trachea, by partially occluding these passages, will prevent the proper expulsion of the secretions below the seat of the diphtheria, and thus set in motion the series of processes that terminate in a more or less inflammatory condition of the lung.

It will be seen that all of these causes are chiefly mechanical in their action, depending upon gross physical changes for their explanation. They can from their very nature only be considered as productive of the pneumonias complicating diphtheria of the upper air passages.

But another more general causative agency in the production of this complication has been revealed by our recent knowledge of the bacteriology of diphtheria and pneumonia. It is the influence of infection. This is by far the most frequent cause of the occurrence of pneumonia as a complication of diphtheria, and is active not only in diphtheria of the larynx and trachea but also in diphtheria of the nose and pharynx; in fact, in any diphtheritic infection of the body. As will be seen when we come to discuss the bacteriology of this form of pneumonia, the streptococcus is the germ most universally present in these cases. Mamorek¹ and other authorities have shown that the streptococci present in various human maladies are really identical. "Each produces indifferently the whole series of the streptococcus maladies depending entirely upon the virulence of the germ and its point of entry." It must be remembered that human beings are more sensitive to the action of these germs than any other living being, that the slightest scratch opens the door to the entrance of these omnipresent cocci, giving rise to inflammations of the various organs to which they are carried, and that streptococci are natu-

rally present even in conditions of health; it will be readily understood, therefore, how in diphtheria, a disease in which the air passages are naturally the seat of irritation, these germs are carried to the lungs. Not only do they there exert their own specific action, but, as Dr. Funck,¹ of Brussels, has shown, vastly increase the baneful activity of the Loeffler bacillus, making the latter far more virulent than in cases of diphtheria the result of a pure infection by the Loeffler bacilli. Dr. Vetter,² in a series of bacteriological studies of broncho-pneumonia occurring in adults and children, found streptococci present in every case of broncho-pneumonia complicating diphtheria, and this authority thinks, that while the infection in broncho-pneumonia is, as a rule, an auto-infection from the mouth and nose, yet the germs here have probably come by contagion originally. It would seem highly probable therefore that the mixed infection of a case of broncho-pneumonia complicating diphtheria can be carried from one to another. This factor is of especial importance in diphtheria hospitals, where children with broncho-pneumonia and diphtheria lie in cots adjoining those that have diphtheria alone. To this cause is probably due the much greater frequency of this complication in diphtheria hospitals, and, above all, the frequent occurrence of broncho-pneumonia in those convalescing from diphtheria in such institutions. Furthermore, cases that have been subjected to operation for membranous croup, either by tracheotomy or intubation, especially where the latter operation has been done under difficulties, are necessarily more disposed to absorb streptococci through the wounds caused by these operations. Without doubt the vastly better results yielded by intubation are due to the greatly diminished danger of the absorption of streptococci in the latter operation as compared with the large wounded surface necessarily the result of tracheotomy. The virus of such a mixed infection reaches the lungs partly by aspiration and partly through the lymphatics. The bacteria thus absorbed become centres for broncho-pneumonia. We believe, therefore, that this complication is produced by auto-infection, or infection from without, or even by contagion. A curious confirmation of contagion as a factor in the production of complicating broncho-pneumonia is my own observation in private practice that when several cases of measles occur in the same family at the same time they do very badly, often developing pneumonia, if they are kept in the same room. I have, therefore, in recent years strenuously insisted upon isolation for each case in spite of the fact that the disease was the same.

As a final element in the causation of broncho-pneumonia as a complication of diphtheria we have the hygienic surroundings of the patient, together with the constitutional condition of each individual. These elements are so well understood as important etiological factors in the production of such a condition as broncho-pneumonia that they require hardly more than mention here. We must not refrain, however, from calling attention to the especial importance of proper air space for individual cases in hospitals devoted to the treatment of infectious diseases. No element is so fruitful in disseminating evil complications as overcrowding. Experience has shown that a floor space of from one hundred and ten to one hundred and twenty square feet is required for each patient in a ward, the height of the ceiling being at least fourteen feet. The temperature of the ward is also of the utmost importance in the treatment of pneumonia. Recent experience in the Willard Parker Hospital seems to show that increasing the air space for each patient

¹ Zeitschrift für Hygiene und Infectious-Krankheiten, Bd. xvii., H. iii.

² Archiv für Kinderheilkunde, Bd. xvii., H. iii.-iv.

¹ Annales de L'Institut Pasteur, July, 1895.

and regulating the temperature to which the air of the wards is artificially raised to not higher than 70° F. has diminished the frequency of and lessened the mortality from pneumonia.

Pathological Considerations.—I have found different varieties of inflammations of the lungs complicating diphtheria. They may be grouped under the following heads: congestion of the lungs, broncho-pneumonia, lobar pneumonia, and gangrenous pneumonia.

Congestion of the lungs, pure and simple, is rarely, if ever, found alone, but it is frequently present as an accompaniment of a localized broncho-pneumonia or bronchitis; this is illustrated by the following autopsy:

Autopsy No. 10.—Subject, M. A.—, age seventeen months.

Clinical diagnosis.—Broncho-pneumonia, right apex; diphtheria.

Anatomical diagnosis.—Broncho-pneumonia, right upper and middle lobes.

Lungs.—Left lung well aerated throughout; moderately congested; bronchi filled with pus.

Right lung, upper and middle lobes consolidated; surface of pleura covered with delicate layer of fibrin. Pleura seat of minute petechial hemorrhages. Cut surface finely granular. Color gray, with reddish tinge in upper portion. Bronchi filled with pus. Lower lobe only moderately congested.

Trachea and larynx contain a little mucus, in which there is a little pus. True vocal cords slightly roughened.

Broncho-pneumonia is the form of pneumonia most frequently found as a complication of diphtheria in children. There are some authorities who doubt whether this is not the only form of pneumonia which ever occurs. While I do not agree with those who hold the latter view, I believe and the autopsies at the Willard Parker Hospital seem to confirm the opinion that almost all of the pneumonias complicating diphtheria are of the broncho-pneumonia type. Nevertheless, I believe that lobar pneumonia does occur as a result of mixed infection. Never can this form of pneumonia occur as a result of the extension of the diphtheritic process into the bronchi and thence into the lungs. Pneumonia which occurs as a result of such extension is invariably broncho-pneumonia. Furthermore, broncho-pneumonia may also occur in discrete or confluent areas scattered throughout the lungs or involving one or both lungs, and yet not as a result of extension of the diphtheritic process into the bronchi by continuity, the larynx and trachea being entirely free, as was shown under the head of causation.

Of cases due to direct extension of the diphtheritic process from the bronchi into the lungs the following autopsies made at the Willard Parker Hospital will serve as examples:

J. P.—, eighteen months.

Clinical diagnosis.—Diphtheria and broncho-pneumonia.

Anatomical diagnosis.—Diphtheria and broncho-pneumonia.

Pleura.—Few petechial hemorrhages.

Lungs.—Left lower lobe, posterior two-thirds, broncho-pneumonia, gray stage. Upper lobe, lower half, also seat of broncho-pneumonia, gray stage. Remaining portions of lung slightly oedematous. Bronchial glands considerably enlarged.

Right lung.—Bronchi contain rather more muco-pus than those of left lung. Posterior two-thirds of lower lobe completely consolidated and also posterior one-fourth of upper lobe showing gray stage of broncho-pneumonia. Remaining lung tissue oedematous. Bronchial glands considerably enlarged.

Pharynx, posterior lateral walls roughened but no

membrane; lower portion much congested. Larynx lined throughout by fairly thick layer of yellowish-white membrane, which is very adherent. Trachea and beginning of primary bronchi lined throughout by thin layer of loosely adherent patchy membrane.

Autopsy No. 11.—Subject, J. K.—, eight months.

Clinical diagnosis.—Pharyngeal and laryngeal diphtheria, broncho-pneumonia.

Anatomical diagnosis.—Tracheal and laryngeal diphtheria, broncho-pneumonia.

Left lung.—Lower lobe, broncho-pneumonia; bronchi contain pus; bronchial glands enlarged.

Right lung.—Consolidation of posterior portion of upper lobe. Lower lobe congested, with a few scattered areas of broncho-pneumonia; consolidated areas of a reddish color.

Pharynx, larynx, trachea, and tonsil covered with membrane. Epiglottis much swollen and covered with membrane.

In these cases of extension of the diphtheritic process into the lungs, the finest bronchioles and air cells may be found lined with false membrane; here the diphtheria exudation is of almost fluid consistency.

The following autopsy is an example of broncho-pneumonia complicating diphtheria. In this case the lung was the seat of tuberculosis in addition to the complications due to diphtheria:

Autopsy No. 9.—Subject, E. S.—.

Clinical Diagnosis.—Diphtheria, broncho-pneumonia.

Anatomical diagnosis.—Broncho-pneumonia, complicated by tuberculosis.

Left lung.—Posterior three-quarters of lower lobe consolidated; lesion presenting appearance of broncho-pneumonia, gray stage. Lower portion of upper lobe contains a few areas of consolidation, portions of which appear to be due to simple broncho-pneumonia; other portions appear to be tuberculous; anterior border of lung shows marked emphysema. Largest blebs one centimetre in diameter. Bronchi contain small amounts of muco-pus.

Right lung.—Same as left, except that the consolidation is less complete; contains only a cheesy nodule near anterior border of upper lobe, one-half centimetre in diameter and partly surrounded with calcareous material.

Pharynx, larynx, and trachea perfectly normal. Some of the bronchial glands are enlarged and calcareous.

This is a case in which the pneumonic process was not the result of extension of the diphtheritic process downward into the lungs, but was independent in origin and due to mixed infection spread by the lymphatic channels, or circulation, or even by aspiration of microbes into the deeper portion of the lungs.

James H. McKee¹ reports a number of cases of lobar pneumonia in children, this in contradiction to the frequently expressed doubt as to the occurrence of such a condition in childhood. Sturges and Coupland found in one hundred fatal cases of diphtheria in children fourteen of lobar pneumonia. While the autopsies made during the past year at the Willard Parker Hospital do not show any cases of death from diphtheria with croupous or lobar pneumonia, yet the clinical course of several cases during my service last summer led me to make the diagnosis of lobar pneumonia. The sudden onset, the well-outlined area of consolidation and the presence of bronchial breathing only in this area, the absence of the signs of bronchitis, generally the absence of diphtheria in the air passages, and the resolution by crisis; all these symptoms point to the probable diagnosis of lobar pneumonia. I am as sure that lobar pneumonia occurs

¹ Archives of Pediatrics, p. 727.

as a complication of diphtheria as I am that it occurs as an idiopathic disease in children.

Finally we come to the cases of diphtheria in which the complicating pneumonia is of the gangrenous variety. Of this variety of pneumonia I saw two cases in 1894 and one case in 1895 at the Willard Parker Hospital. The diagnosis is made by the presence of the usual symptoms of broncho-pneumonia together with the presence of a most frightful odor. Alfieri¹ reports a case of fetid broncho-pneumonia complicating diphtheria, of which he studied the bacteriology. Bernardi reports two cases of the same.

This complication may be the result of large infarctions in the lung, which are sometimes found in diphtheria.

The following is the report of the autopsy of the case seen by me at the Willard Parker Hospital in the summer of 1895.

Autopsy No. 2.—Subject, A. F.—. three years.

Clinical diagnosis.—Diphtheria.

Anatomical diagnosis.—Septic pneumonia, broncho-pneumonia, necrosis, convalescence from diphtheria.

The lower lobe of right lung consolidated, grayish-white, and granular; fibrino-granular pleurisy. Upper lobe contains a number of necrotic cavities filled with thick muco-pus. These occupy most of the lobe. Left lung shows numerous areas of broncho-pneumonia. Parenchyma of organs all show degeneration.

Brain and membranes seem normal and also the spinal cord.

The differentiation of these four varieties of pneumonia—that is to say, (1) broncho-pneumonia resulting from the extension of the diphtheritic process into the lung; (2) broncho-pneumonia occurring as a complication of diphtheria but not as a result of extension; (3) lobar pneumonia, and (4) gangrenous or purulent pneumonia—is important from a prognostic standpoint.

The most important part of our study in the light of present advances in serum therapy is the bacteriology of this complication. It has come to be recognized that pneumonias complicating true diphtheria are not due to the action of the Loeffler bacilli upon the bronchi and air cells, but are rather the result of a mixed infection.

Dr. Vetter² found in seven cases of broncho-pneumonia complicating diphtheria in children that the streptococcus was always present in the lungs. In three cases it was accompanied by the staphylococcus aureus, in one by the pneumococcus, in one by the Friedländer bacilli. Loeffler bacilli were found in four out of these seven cases.

Prudden and Northrup, 1889, found in seventeen children dead of pneumonia complicating diphtheria, streptococci in the lungs as well as in the pseudo-membrane. When pure cultures of these streptococci were injected into the trachea of rabbits, broncho-pneumonia was produced in every case. Whatever may be the causative relation between the diplococcus and lobar pneumonia, it is certain that in every case of broncho-pneumonia pyogenic streptococci are present.³

Mya and also Roux and Yersin showed that injections into rabbits of cultures of Loeffler bacilli and streptococci were far more fatal than diphtheria bacilli alone. Injections of impure cultures of streptococci and staphylococci with Loeffler bacilli were almost caustic in their action, while the general effect was a most virulent one. Injections of pneumococci with diphtheria bacilli show a great increase in the local exudate as compared with that present in animals injected with the Loeffler bacilli alone.

Dr. Funck,¹ of Brussels, injected into guinea-pigs previously immunized to diphtheria by antitoxin, pure cultures of diphtheria bacilli: the result was negative, owing to the immunization. Pure cultures of streptococci also gave a negative result, while the injection of pure cultures of streptococci and diphtheria bacilli resulted in severe sickness and death of the animals. He also found that even the animals injected with the mixed bacteria cultures did not die when the immunization serum had been previously injected in much larger dose than necessary for the quantity of Loeffler bacilli subsequently injected.

From this experiment it appears that an excessive dose of antitoxin would seem to diminish the severity of the effects of even mixed infection.

These experiments also prove the much greater virulence of mixed infection as compared with infection by the Loeffler bacillus alone.

Concetti² injected pure cultures of Loeffler bacilli and obtained the usual results. Other animals he injected with pure cultures of streptococci and staphylococci with negative results, but a third set of animals were injected with a mixture of pure cultures of Loeffler bacilli, streptococci, and staphylococci and the effect was extremely virulent and fatal. From these and other similar experiments the following conclusions are warranted:

1. Streptococci with Loeffler bacilli and with or without other cocci are the bacteriological cause of the pneumonia complicating diphtheria.

2. That mixed infection not only causes this and other complications, but increases markedly the virulence of the action of the diphtheria bacillus.

Even in cases in which the pneumonia is the result of the extension of the diphtheritic process into the finer bronchioles, the active factor in the production of the pneumonia is probably not the Loeffler bacillus, but the pneumonia is the result of the action of the streptococci upon the diseased respiratory mucous membrane.

Platini found that when he subjected animals to inhalation of pure cultures of diplococci, pneumonia did not result unless the mucous surface of the air passages was abraded. Such minute lesions of continuity are produced by the diphtheritic exudate and become the point of entry for the streptococci into the lymphatics and blood.

Symptoms which Characterize the Occurrence of this Complication in a Case of Diphtheria.—The clinical picture of pneumonia is so classical that it would scarcely be in place here to do more than to call attention to such points of interest in the symptomatology of this affection as appear to be of especial diagnostic importance. It is well known that severe and even fatal cases of diphtheria and especially of diphtheritic laryngitis run their course with very little or no rise of temperature. But it may be laid down as an axiom that the occurrence of broncho-pneumonia as a complication of diphtheria is always ushered in by a rise of temperature which remains to a greater or less figure above the normal while the complication lasts. So universally is this true that whenever in a case of diphtheria a sudden rise of temperature occurs, and when a careful examination shows no complication in the kidneys, in the ears, or inflammation of glands, I am led, even before absolute physical signs show the lungs to be involved, to suspect very strongly the occurrence of pneumonia as a complication. If the rise in temperature be accompanied by relatively excessively increased rapidity of respiration and slight cough, I would feel warranted in making a diagnosis of pneumonia long before the physical signs gave any proof of such a condition.

Indeed, the two most important symptoms of pneumonia complicating diphtheria, outside of those obtained by auscultation and percussion, are the rise of temperature and rapidity of respiration greater than would be called for by the increased action of the heart. Of the physical auscultatory signs, those which show the presence of a local capillary bronchitis are extremely important, particularly when this bronchitis is found at the base of the lungs posteriorly. Crepitant and subcrepitant râles in this situation with rapid breathing and rise of temperature indicate when occurring with diphtheria the presence of a broncho-pneumonia. I say this in spite of the fact that I persistently look for bronchial breathing and the percussion note of consolidation. Where the pneumonia begins in the deeper portions of the lungs, signs of consolidation cannot be obtained before the third or fourth day and frequently we do not get them at all, and he who seeks confirmation of his diagnosis by this means will often not find it confirmed until the signs of resolution, moist and subcrepitant râles, defervescence of the fever, etc., show where the lungs have been involved or, in the case of death, the autopsy proves it even more positively.

The most important and, if heard, absolutely pathognomonic physical sign in the early stages of a broncho-pneumonia is one obtained by auscultation. It consists of fine crepitant râles heard on deep inspiration over the inflamed lung tissue. It can be heard in crying infants during the deep inspiration between the cries. Heard once it is so characteristic that a diagnosis of pneumonia can be positively made. The ear of the auscultator should be firmly pressed against the chest, care being taken to exclude the crepitant sound made by the hair of the auscultator rubbing against the chest of the patient. Even if the incipient inflammation be in the deepest part of the lungs and no bronchial breathing or dulness is heard, owing to the overlying healthy lung tissue, this crepitation will be heard on very deep inspiration. It is, of course when certified to by a competent auscultator, absolutely pathognomonic. This crepitation is probably due to the entrance of air through the viscid inflammatory products which partially fill the finest bronchi and air cells in the early stages of pneumonia.

Especially difficult will it be to obtain the classical physical signs in cases of disseminated broncho-pneumonia, for here comparatively healthy lobules surround diseased areas of lung tissue and mask the physical signs, but if one will be guided by the symptoms already given, namely, rise of temperature, increased rapidity of respiration, and the presence of capillary bronchitis, and, best of all, the crepitant râles heard on deep inspiration, he will rarely be deceived in his diagnosis. It is of the utmost importance from a prognostic point of view to attempt to make the differential diagnosis between those cases of broncho-pneumonia which have been caused by an extension of the diphtheritic process through the trachea and bronchi into the lungs and those cases in which the lungs have become inflamed in greater or less areas without the respiratory mucous membrane intervening between the seat of disease in the throat and that in the lungs being affected by diphtheria. Fortunately it is generally easy to follow the course of disease in those cases of laryngeal diphtheria in which the process spreads downward through the trachea and bronchi into the lungs. There will be the coarse bronchial râles in disease of the bronchi, then fine sibilant râles showing its progress into the capillary bronchioles and almost at the same time crepitant and subcrepitant râles indicating the involvement of the lungs. If a considerable area of lung tissue has become involved, the prognosis in these cases is extremely fatal. Indeed, even when at first but a small

portion of lung tissue is involved the process is apt to extend very rapidly. Some portions of lung tissue which do not become inflamed are apt, through the closing of their terminal bronchioles and consequent imperfect inflation, to be the seat of atelectasis. Furthermore, vesicular emphysema is apt to incapacitate portions of lung tissue that have remained healthy so far as the inflammation was concerned, so that in these cases the prognosis is almost certainly fatal.

Isolated patches of broncho-pneumonia, even when of considerable size, provided the larger bronchia are not the seat of diphtheria, as a rule give a much better prognosis than broncho-pneumonia the result of extension of the primary disease as above described.

Lobar pneumonia, although its occurrence as a complication of diphtheria is much rarer than lobular pneumonia, has a comparatively good prognosis, more favorable than that of broncho-pneumonia even of the latter variety. It resolves by crisis and, as a rule, in much shorter time than broncho-pneumonia. Septic or gangrenous pneumonia, it is unnecessary to say, is absolutely fatal.

Furthermore, the prognosis depends upon the severity of the diphtheritic process, the stage of the disease in which the pneumonia has occurred, the surroundings and strength of the patient, and finally as to whether the case has been operated upon or not. Pneumonia complicating tracheotomy is, as a rule, almost certainly fatal, but in pneumonia complicating cases that have been intubated, while the prognosis is very grave, still it is better than in similar cases that have been tracheotomized.

While we can only accentuate the gravity of pneumonia complicating diphtheria, it is but proper to remember that, taken all in all, a great many cases recover from even this serious condition.

Treatment, Prophylactic or Preventive.—This being a disease due primarily to bacterial infection, it necessarily follows that cases of broncho-pneumonia complicating diphtheria should be isolated from other children having diphtheria. Indeed it would be perfectly proper to go further, were that the object of this paper, and lay down the general rule that all cases of pneumonia should be isolated from persons in health in order to prevent infection. The fact that broncho-pneumonia is so much more prevalent in diphtheria hospitals than in private houses where single cases of diphtheria occur is probably due, first, to this contagious element in broncho-pneumonia; second, to the fact that the air of the hospital ward in which many cases of diphtheria lie becomes surcharged with bacteria, especially with streptococci. Hence it follows that cases of broncho-pneumonia occurring in diphtheria hospitals should not only be isolated, but that even cases of diphtheria uncomplicated by broncho-pneumonia should have allowed a much larger air space for each patient than is given in general hospitals to each bed. The ventilation should be perfect, the air of the ward being frequently changed without the production of a draught. The temperature of the ward should be kept at 70° F. in order to avoid weakening the patients by too warm an atmosphere. The latter precautions as to ventilation and temperature should be followed in private houses also, wherever a case of diphtheria is being treated.

Cases that have been intubated and above all those that have been tracheotomized should be carefully guarded from contact with cases of broncho-pneumonia, for, as I have already said, micro-organisms are generally active in the production of this complication when the mucous membrane of the respiratory tract has undergone a lesion; this is apt to be the case in intubation and it certainly occurs in tracheotomy. In intubated cases it is further necessary that great care be taken in feeding, that liquid particles of food do

not regurgitate into the larynx and thus produce "Schluckpneumonie." This can be, to a great extent, prevented by feeding the child in the supine position, with the head thrown well back over the edge of the couch or the lap of the nurse.

Curative Treatment.—We can do nothing locally to treat the seat of disease. I say this in order to discourage the treatment of broncho-pneumonia by inhalations of antiseptic vapors. I do not think that such vapors retain any of their germicidal properties when they reach the seat of disease in the finer bronchioles and air-cells. In spite of the fact that comparatively weak solutions (vaporized) of various antiseptics destroy the streptococcus, the germicidal treatment of broncho-pneumonia is impracticable. Inhalations of oxygen, however, are useful, partly as heart stimulants, partly to enable the crippled lung to do the work of a healthy one by absorbing oxygen in a more concentrated form than in the ordinary air. For the reduction of temperature antipyretic drugs should be avoided; the cold pack is by far the best antipyretic agent. Children can be wrapped in sheets wrung out of ice water every half-hour until the temperature is reduced to a proper degree. These cold sheets act not only to reduce temperature but stimulate the patient. Furthermore, they have a local effect upon the lungs to reduce the inflammatory congestion. With this object in view I order the chest of children with pneumonia in the earlier days, in whom the temperature is not very high, to be wrapped in cold compresses wrung dry from ice water, regularly every hour or as often as they become warm. Counterirritants of various kinds applied to the chest are also useful. Poultices should never be used. At the instance of my colleague, Dr. Brannan, who tells me that he owes the suggestion to Dr. Seymour, of Troy, we are accustomed at the Willard Parker Hospital to raise the foot of the bed of children that have been intubated to the extent of ten or twelve inches, with the object of draining away the discharges, etc., by gravity into the pharynx. Of constitutional remedies we have a great many, the object being to support the vitality of the patient by food, stimulants, etc., and such drugs as maintain the action of the heart, such as ether, nitroglycerin, caffeine, and alcoholic stimulants, for a temporary effect, and digitalis and strychnine for more continued action. In addition to all this antitoxin and other remedies for the diphtheria of which the pneumonia is a complication must be used. In view of the fact that excessive doses of antitoxin have been shown experimentally in animals to protect to a certain extent against even mixed infection, cases of broncho-pneumonia complicating diphtheria should have extra large doses of antitoxin administered.

Here, however, I wish to consider an entirely new remedy that has been used in Paris to a limited extent in broncho-pneumonia complicating diphtheria, as well as in other streptococcus diseases, and that is the use of the antistreptococcus serum. It is self-evident that the application of the serum treatment to the cure and prevention of this complication depends upon the certainty of our knowledge that pneumonia as a complication of diphtheria is caused not by the Loeffler bacillus but by a mixed infection in which the streptococci take a very important and constant part. Of those who have sought to find an antistreptococcus serum as well as an antitoxic serum for the poison of the streptococci, the best work has been done by Dr. Alexander Marmorek.¹

He proves first that different forms of streptococci are varieties of a single microbe. Thus, he believes that Fehleisen's erysipelas streptococcus can not only

produce erysipelas, but when sufficiently virulent can produce meningitis, pneumonia, abscess, and septicæmia. It depends upon the degree of virulence of the streptococcus as well as upon the point of its entry into the body as to what disease shall be produced. To demonstrate this his first care was to increase the virulence of a given form of streptococcus.

As a culture medium for streptococcus he used one part of human-blood serum obtained from the fluid of ascites and two parts of beef bouillon, or two parts of horse's or mule's serum and one part of bouillon. To increase the virulence of the streptococcus it is necessary to inoculate a sensitive animal with a fatal dose of the pure culture of the streptococcus. A second animal is then injected with a fatal dose of culture from the blood or juices of the organs of the first animal, and so on uninterruptedly. After two months the virus has become so strong that a single microbe introduced under the skin of a rabbit is fatal to the animal. This is necessarily the physical limit to which the virulence of the streptococcus can be increased. These latter virulent cultures of streptococci killed sensitive animals by septicæmia irrespective of the disease from which the streptococcus was originally obtained.

This streptococcus culture thus enormously increased in virulence is used to render immune less sensitive animals, as the horse. Man is one of the most sensitive animals to the action of the streptococcus, and it is evident that in the search for a curative serum against this microbe we shall have to use the blood of animals immunized against the most virulent streptococci. The ideal serum will be that obtained from animals immunized against streptococci infinitely more virulent than any to the action of which man can by any possibility become subject. The smaller sensitive animals will not support the injection of such virulent streptococci, and it is found that the horse is the best animal for the purpose; being less sensitive he supports without a fatal result more virulent and larger doses of streptococcus cultures. The process of immunization consists in injecting under the skin of the horse small doses of a culture of an extremely virulent streptococcus, which is followed by more or less reaction and sickness. The animal is permitted to recover its health; then another injection is made, increased in quantity and sufficiently large to be followed by an energetic reaction. Thus, a young horse weighing 240 kilograms received 5 c.c. of a pure culture of an extremely virulent streptococcus followed by a rise to 40° C. in temperature; this quantity was doubled at each subsequent injection; so in five months this pony received thirteen injections, in all about 195 c.c. of pure culture. Then the serum of the animal gave satisfactory results.

The serum should not be taken from an immunized horse for therapeutic or even experimental laboratory use until three or four weeks after the symptoms of reaction, such as fever, etc., following the last injection have subsided.

It is apparent that these animals are immunized against the streptococcus and not against the toxin produced by the streptococcus, so that the curative and protective serum obtained from these animals is not a streptococcus antitoxin but an antistreptococcus serum. The attempt has been made to immunize horses to the toxin produced by the streptococcus, but it is very difficult to obtain a toxin sufficiently virulent to be of any use in immunizing horses. Until such is obtained a streptococcus antitoxin will be out of the question.

That the antistreptococcus serum is also antitoxic in its action, however, is shown by the fact that a rabbit injected with 1 c.c. of the strongest streptococcus toxin prepared in the laboratory had at the same

¹ Annales de l'Institut Pasteur, July, 1895.

time an injection of 5 c.c. of the antistreptococcus serum, and death did not occur.

It will be readily seen that for the purpose of treating pneumonia complicating diphtheria the serum of a horse immunized to the action of diphtheria toxin and streptococci cultures would be ideal, inasmuch as such a serum would have diphtheria antitoxic as well as antistreptococcus properties. The attempt has been made by Marmorek to immunize a horse to both streptococcus and diphtheria toxins. It has been found that horses already immune to diphtheria toxin can stand very much larger doses of the streptococcus culture than horses not thus immunized. Such a serum has been experimented with in Paris, but the results are as yet insufficient to warrant any real conclusions.

The strength of the antistreptococcus serum is measured by the quantity necessary to render a rabbit insensible to the action of ten times a fatal dose of pure culture of streptococcus, the protective serum having been injected twelve to eighteen hours before the culture. The strength of the serum prepared by Marmorek has been such that 100 c.c. has been a potent dose. This dose has been repeated in twenty-four hours if improvement has not set in. Marmorek has used the antistreptococcus serum in scarlet fever, in erysipelas, in pseudo-membranous pharyngitis and tonsillitis, and in diphtheria cases in which Loeffler bacilli and streptococci were shown to be present. In erysipelas the death rate was reduced by one-half as compared with cases not treated by the serum. In scarlet fever complications were very much diminished in frequency.

The bacteriological laboratory of the New York Health Department is now engaged in the production of an antistreptococcus serum as well as a streptococcus antitoxin. As soon as a serum of sufficient protective power has been obtained, it will be possible to use it for clinical purposes. The use of such a serum in diphtheria will be, however, principally on a different basis from the use of the diphtheria antitoxin, for while the latter is used to cure an already existing diphtheria, the antistreptococcus serum or antitoxin will find its chief use in preventing such complications of diphtheria as broncho-pneumonia. I believe, therefore, that, with isolation of pneumonia cases in diphtheria hospitals, and with the use of antistreptococcus serum or antitoxin in cases in which a bacteriological examination shows the presence of streptococci of Loeffler, the present mortality from diphtheria and the frequency of broncho-pneumonia as a complication of this disease will be very much diminished.

245 SEVENTH STREET.

Told in Chicago.—Freddie had the croup and Mr. Burton dressed hastily with the help of his wife, who insisted upon his taking his revolver, and rushed out for the doctor.

The night was very dark and in going around a corner Mr. Burton collided heavily with some one and then jumped backward.

"Excuse me," said the man and walked on.

Burton grasped his weapon, thought a moment, felt for his watch; it was not there, the man had taken it.

Burton drew his revolver and shouted: "Stop, or I'll shoot." The man stopped. "Now," said Burton, "give me that watch." The robber handed it over.

Burton returned and related his adventure, only to learn that his wife had removed the watch before he went out. A half-hour later the doctor came in somewhat agitated and explained that while returning home from an urgent case he had been held up by a most villainous-looking highwayman and robbed of his watch.

Clinical Department.

A NEEDLE IN THE FOOT DEMONSTRATED BY ROENTGEN RAYS.

BY WILLIAM JAMES MORTON, M.D.

OPERATION AND ITS DESCRIPTION BY RAMON GUITÉRAS, M.D.

History.—Mrs. I. W.—, aged thirty-six, on July 4, 1885, pushed her foot along the carpet of the floor and felt a needle puncture the foot and break off. She pulled out about two-thirds of this needle, leaving the other third. It was a very fine cambric needle and the part broken off and in the foot was the sharp end. By December she experienced much pain in her foot and she had suffered much pain ever since. The pain frequently woke her in the night. She frequently removed her shoe to relieve pain, as, for example, when at the theatre or while riding in the street or elevated cars. She had never been able to locate the site of the needle within several inches, but thought it might be at about the centre of the ball of the foot. No attempt under these circumstances had been made to extract it by surgical operation.

Shadowgraph.—The case seemed a most unpromising one to attempt. The needle had been in the foot eleven years and might be very much oxidized. It was, moreover, an extremely small object and might be located on top or beneath the bone. I resolved to expose long enough to entirely obliterate the shadowgraph of the bones themselves, hoping to leave a shadowgraph of the needle only. To obtain a picture of the bones would be easy, but if the needle happened to be on top of or behind a bone it would not be revealed.

A static machine with Leyden jars was employed to excite the vacuum tube. This was not a Crookes' tube, but a bulb devised by myself for this work, having one or more external electrodes of tinfoil. The plantar surface of the foot rested upon the plate-holder containing a 6x8 inch plate, while the vacuum tube was supported above the dorsal surface. To ensure obliteration of the skeletal bones an exposure of one and one-half hours was given.

Upon developing the plate I could see nothing of moment upon it in the dark room, except that the radiation had in truth freely traversed the bones, but after washing the negative and holding it up to the light to examine it, the needle showed up plainly and in quite an unexpected position. Taking the negative for comparison, I pressed my thumb nail into the flesh of the plantar surface of the ball of the foot at the spot indicated by the shadowgraph, and the patient at once flinched and exclaimed, "Oh, that is the spot! It hurts when you press upon it just like the prick of a needle." The discovery of this location was entirely unexpected by the patient, for she had never before realized any especial sensitiveness in that particular spot.

The foreign body having been localized, the patient was anæsthetized and the foot prepared for operation. An incision was then made by Dr. Guitéras over the outer border of the metatarso-phalangeal articulation of the fourth toe. This extended through the skin and plantar fascia down to the layer of superficial muscles. The margins were then retracted, displaying a mass of fatty tissue. This was carefully dissected away and the deeper structures were brought into view, that is, the flexor longus and brevis digitorum and the arteries and nerves going to this toe. The end of the finger was then inserted and an attempt made to locate the needle by the touch. A hard wiry body was felt just to the outer side of the tendons, which was clearly appreciable when pressure

was made against the ends of the bone going to form the metatarso-phalangeal joint. We at once concluded that this was the needle and proceeded to approach it with great care. The tendons going to the toe were carefully drawn to the inner side by retractors and the wiry body was seized with the thumb forceps and examined. It did not prove to be a needle, however, but an enlarged and indurated nerve going to the outer side of the fourth toe. The incision was, therefore, made a little longer and deeper, so as to extend between the bellies of the interossei muscles, and a part of the transversus pedis muscle was cut through. This gave a better view of the field where the needle had been located by the photograph. The nerve about which there was a dark discoloration could now be clearly seen. The capsular ligament over which the nerve ran was also discolored in this area and was very much thickened.

A careful dissection was now made about the ends of the metatarso-phalangeal bones going to form the joint of this toe, but there were no further evidences of a foreign body.

It seemed probable, therefore, that the needle had been embedded for a long time in the tissues between the interosseous muscles on the outer side of the plantar surface of the capsular ligament covering the metatarso-phalangeal articulation of the fourth toe, along which region the fifth digital nerve passes; that time had served to cause a chemical decomposition of the needle, thus producing the localized discoloration, and that the constant irritation excited by the foreign body had set up a chronic inflammation of the nerve, resulting in a thickening and an induration, the pressure on which had caused considerable pain.

Accordingly about three-quarters of an inch of the nerve was excised and the wound was closed.

Comments.—The location of the needle based upon pressure and the sensation of the patient and the operation itself demonstrated that the needle, or rather its corroded and oxidized remains, was situated directly behind the bone. That is to say, the bone intervened between the vacuum tube and the sensitized plate. To delineate this needle the bone itself had to be penetrated by the Roentgen radiation. That it was so delineated opens out greater possibilities of the utility in surgery of the Roentgen process, for we may be able not alone to detect foreign bodies behind or within bone tissue but also to picture morbid processes inside of the bone.

That the needle had become oxidized and corroded to a mere line of oxide is corroborated by the experience of several physicians I have talked with who have removed needles resident a much shorter time in living tissue and yet even then showing this condition.

Under the circumstances of thickness of tissue, of smallness of the object sought, and success in picturing and removing its remains, the case teaches us more than if the foreign body had been of greater size.

Varicose Veins.—J. E. Summers (*Transactions of the Neb. Med. Soc.*) says that, according to Trendelenburg and Willie Meyer, if a limb be elevated and stroked toward the body a dilated vein collapses. If pressure is then made and maintained over the internal saphenous vein below the saphenous opening, the limb may be lowered without a return to the varicose condition, as the weight of the column of blood is removed. Following up this idea, they apply a ligature to the vein at its entrance into the saphenous opening, and in severe cases remove the main trunk and enucleate or ligate a large part of the vessels in several places above the knee, and also the branches entering it.

A CASE OF ABSOLUTE LOSS OF SMELL AND TASTE.

By A. SCHIRMAN, M.D.,

NEW YORK.

A. M—, aged twenty-nine, a stout workman in an iron factory, was struck on the head while at work by some pieces from a burst emery wheel. He was thrown backward and fell on the ground. He had an immense contused and lacerated wound with ragged edges on the scalp in the region of his right temporo-occipitalis over the eminences, but more toward the front. The wound bled profusely and the surrounding tissues became swollen. The patient lay unconscious, with stertorous breathing, but there were no convulsions or spasms of the facial muscles nor was there any paralysis of the masseteric or mimetic muscles of the face. There was no indication of hemiplegia. An ice bag was applied to the injured head of the patient by surrounding friends until he was restored to consciousness.

When I came to his home I found him in a state of great nervous prostration, being disinclined to reply to my inquiries, but he gradually became wonderfully improved and answered my questions about his case more readily. After the occurrence of the catastrophe, as I was told, he was taken in an ambulance to a hospital, where he remained in the emergency ward three hours only, not desiring to stay there longer.

After my examination I dressed the lacerated wound over the frontal eminence and ordered absolute rest in a dark room, with applications of dry cold over the bandage by aid of an ice bag. After eight weeks' treatment the patient recovered, to all appearances perfectly, having no irregularity in respiration, pulse, or temperature. His appetite, the secretions, and the power of sleep were in good order. The external wound, which penetrated to the pericranium, healed entirely in less than a month. But many weeks after his apparent recovery the patient noticed that his sense of taste was nearly gone. He recalled then that during his illness all the drugs and medicines and even the food which he had taken seemed to be tasteless. And now he began to realize that this defect of the sense of taste was independent of his previous ailment. He observed also that the sense of smell was lost.

I was told by the patient that after the loss of his senses occurred he was advised to try insufflation of snuff as well as of other sternutatories and to take bitter drugs, but he obtained no relief whatever from their use.

Upon careful examination I noticed that the scar previously mentioned was adherent to the cranium along a distance of four or five inches: it was slightly tender on pressure. The man had no paralysis nor any contraction of the facial muscles. There was neither anæsthesia nor hyperæsthesia present. The salivary secretions were of normal quality and quantity and the tongue could be extended without deviation to either side.

Examination of the sense of taste revealed the following: Whenever a moderate solution of salt, vinegar, quinine, or sugar was applied to the tongue, the patient felt a very slight gustatory impression, though these substances were distinguished correctly. With concentrated solutions of the same materials the patient (with closed eyes) was doubtful or else he failed entirely to determine their character.

The sense of touch was intact. It was noticeable, when the periods between my investigations were of longer duration and the patient after each trial rinsed his mouth thoroughly, that he was able to define more distinctly the taste or the bouquet of any par-

ticular kind of food by applying it at the front part of the tongue.

I did not have the chance to try the acuteness of the gustatory sense by the galvanic method, as suggested by Dr. Newman. This test is well appreciated in the examination of pathological cases.

Examination in regard to the sense of smell showed that the sense of touch in the nasal mucous membrane was normal, for he felt all irritating, caustic substances, which he evidenced by sneezing after insufflation of tobacco, inhalation of ammonia, etc., but the sense of smell was entirely absent.

With closed eyes, he even by forcible inhalation could not differentiate the odor of volatile oils, of eau de cologne, camphor, or St. Ignatius' beans. Upon irritating the upper part of the nasal septum (where the olfactory nerves end) with a strong aroma, he felt an unpleasant tickling sensation, accompanied by a flow of tears from the corresponding eye.

The other special senses did not exhibit any abnormal character.

The above-described case was, therefore, one of unilateral ageusia and bilateral anosmia as a result of a cranial injury.

In deciding which nerves governing the functions of smell and taste were affected by the trauma we must exclude the chorda tympani and the lingual branches of the trigeminus, for there was no loss of ordinary sensation nor of the power of motion in the tongue.

Examination of the tongue revealed a loss of gustatory sensation on the back part of the dorsum of the tongue, where the ends of the glosso-pharyngeal nerve are distributed.

Therefore, excluding the branches of the fifth and seventh nerves, we must accept as the cause a derangement of the first and twelfth or of certain points of the brain substance connected with them.

The hypothesis of a derangement of the olfactory and glosso-pharyngeal nerves is here unlikely, because their cerebral origins are found anatomically far apart in the intervals and separated by various nervous centres. As a result of injuries of these adjacent centres there should be more grave symptoms symmetrically associated with two points in each hemisphere (four in both). Here this was not the case. Therefore we are forced to locate the trouble in the cerebral centres governing the senses of smell and taste. These senses of smell and taste have been located in that part of the brain which is called the gyrus hippocampi. This has been shown experimentally by Claude Bernard, Magendie, Meynert, and others. By destroying these centres the two special senses were completely lost. So we can conclude that the trouble was more probably a lesion of certain cerebral parts rather than of the first and twelfth cranial nerves. In this case the patient suffered with bilateral anosmia. For this occurrence a probable explanation may be found in the fact asserted by Meynert, that in the anterior commissure there is a crossing of the filaments of olfactory nerves; that this crossing can be seen very distinctly in the lower animal (dogs, cats, rabbits, monkeys, etc.), in which the olfactory lobes are much more developed than in man. Thus, if we admit a connection between the two olfactory centres, there would be no wonder that the patient with cerebral destruction in the hippocampal gyrus of one side should suffer at the same time with some disturbances on the other side.

Gratifying to Smokers.—Professor Hajak, of Vienna, says smokers are less liable to diphtheria and other throat diseases than non-smokers in the ratio of one to twenty-eight. Dr. Schiff tells us that smoking is forbidden in bacteriological laboratories because it hinders the development of the bacteria.

GUNSHOT WOUND OF THE NECK FOLLOWED BY ANEURISM—DELIGATION OF THE LEFT COMMON CAROTID—RECOVERY.

By E. C. CARTER, M.D., ASST. SURG., U. S. A.

J. C—, private, Troop "D," 10th Cavalry, aged twenty-three, was shot by a comrade with a revolver, calibre 38, about 6:30 P.M., June 13, 1895.

The ball entered the back of the neck one and one-half inches to the left of the median line and one and one-half inches above the seventh cervical vertebra, and ranged horizontally forward. The aperture of exit was one-half inch to the left of the median line of the lower jaw and one-half inch below the mental tubercle.

The ball passed between the vertebral column and the great vessels of the neck, wounding some of the latter. There was great shock with irregular action of the heart—at times slow, at times rapid and tumultuous, due probably to injury of the pneumogastric nerve. There was considerable hemorrhage from the aperture of entrance, perhaps a pint or more. This hemorrhage was easily checked by pressure. A tumor three by four inches formed under the left angle of the inferior maxilla. When shot the man fell on his hands and knees, asked "Who shot me?" and became unconscious. He remained unconscious and in convulsions for some hours. Next morning his condition was more satisfactory. The wound healed rapidly superficially. The size of the swelling under the jaw diminished gradually, but a small pulsating tumor about the size of a pigeon's egg remained. Surgical interference was contemplated, but after consultation with Dr. C. F. Kieffer, U. S. Army, who gave me valuable aid throughout the case, it was decided to wait, keeping the patient under observation. About July 10th the patient was considered to be in sufficiently good condition to make a railway journey of some hundred miles to appear before a United States court.

After his return the symptoms gradually became graver. He was losing flesh, becoming weaker. He suffered pain in the left side of head and neck. Hearing in the left ear was about one-half, vision of the left eye two-thirds. Ptosis of the left eyelid developed. On protrusion the tongue was deflected to the left side. The pulsating tumor was increasing in size, but apparently was working away from the carotid artery and jugular vein. On July 30th it was decided to operate. The patient was carefully prepared. Ether was given and under strict antisepsis the sheath of the left carotid was exposed. The track of the ball was visible passing beneath and very close to the carotid about its bifurcation. The lingual artery seemed to have been injured at its origin. Pressure on the common carotid caused the pulsation of the aneurism to cease. The sheath of the common carotid was exposed and two strong silk ligatures were firmly tied round the artery. About six ounces of blood were lost, owing to the cutting of some veins of the thyroid plexus.

The patient's heart action was quite weak until a hypodermic injection of atropine was given, after which he rallied well. The wound healed fairly rapidly. The ligatures did not come away until October. The man has been returned to duty, and except for a slight degree of ptosis seems to be as well as ever.

My thanks are due to Assistant Surgeon C. F. Kieffer, to Stewards Erck and Stoddard, U. S. Army (who aided in the operation), and to Assistant Surgeon P. R. Eagan, U. S. Army, who informed me of the final disposition of the patient.

RESECTION OF THE PYLORUS WITH ANASTOMOSIS OF THE INTESTINE AND STOMACH WITH THE MURPHY BUTTON.

BY M. H. EVERETT, M.D.,

LINCOLN, NEB.

J. J. H.—, aged thirty-five, native of Bohemia. Eleven years ago he began to have indigestion and pain in the stomach and back; from that time he was never free from distressing symptoms in his stomach that were but little relieved by treatment. Five years ago the disease gradually increased so that he began to vomit daily and the pain in the stomach and back was most distressing. The vomiting would give him relief for a few hours. In November, 1894, he came under my care, when his condition was found to be as follows:

Height, 5 feet 2 inches; weight, 95 pounds; very much emaciated and with a melancholic expression. Complained of pain almost constant in the back and stomach; he had but little appetite and frequent eructations of gas. The stomach was much dilated, and a tumor could be felt through the thin abdominal wall a little to the right and above the umbilicus; the vomiting usually occurred in the late afternoon or evening and ceased when the stomach was empty. The nature of his trouble was explained to him and an operation proposed, to which he readily acceded. He was very weak and it was with difficulty that he could move around. It was feared that he had not strength to stand the operation, but he insisted, saying that if I did not do something for him he would take his life, as he could no longer stand the continual suffering.

On December 18th the abdomen was opened in the median line above the umbilicus and the tumor with a part of the intestine brought out; the stomach had been previously washed out. The growth was found to be as large as a hen's egg; no adhesions were found; the tumor embraced about two inches of the intestine and projected into the stomach, the walls of which were thickened for some distance from the tumor. The omentum was ligated as far as necessary; the incision in the stomach was made one and a half inches from the growth and the stomach was closed with the Czerny-Lembert suture. The growth with about two inches of the intestine was then removed; a new opening was made in the posterior wall of the stomach about two inches from the sutured end and the intestine was joined to the stomach with the Murphy anastomosis button, certainly not more than five minutes being occupied in making the anastomosis. The stomach was dropped back and the abdomen closed. He left the table with a pulse of 106 and soon rallied from the shock of the operation. The temperature never rose above 99° F. Water was felt to pass through the button on the fourth day, which had the effect of dispelling the man's melancholy; his appetite soon returned and before he was allowed to get out of bed he was ravenously hungry in spite of the liberal feeding that had been allowed after the first few days. The button was passed a few hours before the end of the fourteenth day.

The result of the operation was truly gratifying; he soon began to gain in weight and now weighs 152 pounds, a gain of 57 pounds. He is now at the end of one year in absolute health and is not conscious that he has a stomach. I feel certain that the happy outcome of the operation was secured by the use of the Murphy button. In his weakened condition the patient could hardly have survived the increased time that would have been necessary if the anastomosis had been made by suture. The growth proved to be a fibroma embracing the whole circumference of the pylorus and completely closing it.

Progress of Medical Science.

The Diagnosis of Syphiloma.—Professor v. Esmarch, according to *Medicine*, assures us that he has sometimes mistaken syphilomata for malignant tumors on account of the great physical similarity between these two diseases, and assumes that many others have done likewise—in fact, he quotes such cases from the published experience of others. He regards as untrustworthy the diagnosis of malignant tumors: (1) When the patients have symptoms of syphilis present or past, or where the history shows that they, their parents, their brothers, or their sisters have suffered from this disease; (2) when the tumors develop in the voluntary muscles, for syphilomata occur in the muscles much more frequently than do other forms of tumors—they are most frequently found in the sternomastoid (one-third of all the observations), then in the muscles of the abdominal wall, the back, the legs, and finally in the tongue muscles; (3) when the tumors (sarcomatous) return shortly after extirpation—perhaps to this class belong the recurrent fibroid tumors of Paget; (4) when the tumors disappear after the use of iodide of potassium, mercury, and Zittmann's cure. An example of such mistaken diagnosis is the case of a patient whose earlier history has only recently been brought to light. In 1886 a man aged forty-two presented himself with a number of ulcers of a syphilitic character and numerous scars, the evidence of repeated extirpations and erosions. The physicians of California had regarded his disease as carcinoma, which was supposed to have arisen as the result of a hammer stroke upon the penis, and they removed the diseased tissue and the recurrent masses. Finally the penis, the scrotum, and the testes, as well as large pieces of the abdominal skin, were cut away. Esmarch observed the opening of the urethra at the apex of a skin mass at the side of the median line and subjected the unfortunate fellow to an energetic antiluetic cure, and after the use of a considerable quantity of mercuric ointment and iodide of potassium all the tumors were cicatrized. Professor von Esmarch also states that he regards as genuine the cases of sarcomata reported by Dr. William B. Coley, of New York, as having recovered under the influence of erysipelas and prodigious toxins, for the reason that they all bore much the same clinical appearance and because the carcinomata, which are not so readily confused with syphilis, were not at all affected by the treatment.

Congenital Atresia of the Hepatic Duct with Cirrhosis of the Liver.—Dr. McCallum has reported the case of a male infant four months old, born at term, with a history of jaundice dating from a fortnight after birth. The discoloration had progressively increased despite medication. At the age of eleven weeks the left eye became severely inflamed, leaving a scar upon the cornea. For a week there had been cough. The child had always taken the breast greedily, but for two days it had vomited curdled milk. The bowels were constipated and the evacuations were pale, as a rule yellow, but sometimes greenish. The urine stained the napkins a coffee color. There was no history of hemorrhages and no cause could be assigned for the condition; a history of syphilis could not be elicited. The liver was enlarged and an umbilical hernia existed. Later the child was seized with convulsive movements and vomited coffee-grounds material. Death took place two days after the little one came under observation. Upon post-mortem examination, in addition to the general icteric discoloration the lungs presented numerous deep-blue patches, some of considerable size,

extending into the pulmonary structure, in the case of the larger ones to an appreciable depth. Similar isolated patches were also present in the midst of the pulmonary tissue. These were found to be hemorrhagic areas. The liver was of a deep-brown color generally, but its upper surface was paler. The organ presented a finely granular aspect. The gall bladder could not be seen projecting from the anterior edge, and careful examination revealed in a recess on the under surface only a greatly shrunken and flaccid structure. A bristle introduced into the papilla in the duodenum passed freely upward toward the transverse fissure of the liver. The duct was found to be continuous with the cystic duct, passing onward with a sigmoid curve to the empty gall bladder, which was found collapsed and misplaced. No trace of hepatic duct could be found except a thin, white cord. The liver, which was tough on section, presented no appearance of dilatation of the ducts. In the neighborhood of the duct and of the transverse fissure of the liver were a number of enlarged glands presenting a deep-brown color resembling that of the spleen, and there were also glands in the abdomen not so much enlarged but similarly colored. Microscopic examination showed an extraordinary degree of cirrhosis of the liver.—*Archives of Pediatrics*.

The Relationship between Auto-Intoxication and Neurasthenia.—According to *The Practitioner* Dr. Alvis Pick accepts Baumann's discovery of the presence of certain aromatic bodies (indol, scatol, paracresol, phenol, etc.) in the urine of man and some animals, and discusses at length their mode of production in the body. Indol, which he takes as a type, is found in such conditions as intestinal obstruction, atony, paralysis, etc. It is eliminated partly in the fæces and partly in the urine. These bodies act as poisons in the blood and produce auto-intoxication. The manner in which auto-intoxication is modified or prevented is next discussed, stress being laid on the anti-putrefactive properties of the HCl in the gastric juice. The biliary and pancreatic juices also have a preventive property, so also have the fatty acids, resulting from splitting up of the carbohydrates. If these natural safeguards fail, blood poisoning results. Uremia is possibly a form of auto-intoxication. Possibly this may result from an excess of normal urinary constituents, but von Noorden states that uramic poisons do not exist in the normal constituents, "but that, primarily from reaction upon the tissue in retention, opportunity is given for the production of poisonous substances from natural metabolic products." The author next discusses the *modus operandi* of certain articles of food (shellfish, strawberries, etc.) on some persons as poisons. There is reflex action, but this is the path of morbid action, not its cause. There must be (1) individual predisposition; (2) poison introduced into the blood from (a) improper ingesta (decomposing sausage, fish, etc.), or (b) it may originate in the intestine from the combined action of putrefaction and certain micro-organisms. Similar symptoms may arise from such drugs as antipyrin, iodoform, etc. In these cases the skin is often affected (erythema, urticaria, etc.), but other organs are also affected. Hence some cases of pernicious anæmia originating in gastrectasy may be cured by lavage of the stomach. Auto-intoxication produces marked nervous phenomena, which may be classified thus: 1. Giddiness; sometimes a true vertigo *a stomacho læso*. 2. Headache; this is common in habitual constipation with urine loaded with indican. 3. Heaviness and sense of pressure on head. 4. Cerebral vomiting due to poisoning of the medulla. 5. Convulsions. The author had a patient who had convulsions soon after meals and was cured by antifermenta-

tive treatment. 6. Psychical disturbances. Delirium with normal pulse and temperature. Insanity is often associated with obstipation and is relieved when this is cured. Irritable temper and hypochondriasis are other symptoms. 7. Peripheral nervous symptoms, such as tremor. There may be all the symptoms of Basedow's disease, and the author believes that this affection may sometimes originate in auto-intoxication. These symptoms, which may arise singly, in association, or one after the other, afford a picture of true neurasthenia, and Pick believes that many, though not all, cases of neurasthenia originate in auto-intoxication. The author refers to the most frequently alleged causes of auto-intoxication—*e.g.*, over-fatigue, sexual excesses, mental anxiety, etc.; and adds that the disease is more common among indolent than among energetic persons. He next discusses the pathogeny of auto-intoxication, and says that in medicine it plays a similar rôle to wound infection in surgery. In the third article treatment is discussed. Diet is of most importance. Food rich in albumin and carbohydrates should be given, and milk is very useful. Generally a mixed diet of eggs, flesh, milk, vegetables, and farinaceous food is to be recommended. Therapeutics are directed by etiological considerations. Sluggish gastric movements should be stimulated by massage, electrical abdominal sponging, douching, etc. Internal antisepsis should be aimed at, and calomel (gr. ss. *ter in die*) is useful in this way. The intestinal tract must be kept clear by purgatives, lavage, massage, etc. Antifermentatives, such as creosote, menthol, guaiacol, phenol, etc., are also advisable.

The Pathology of Appendicitis.—Professor Dieulafoy asserts that recent experiments by Dr. Rendu on appendicitis confirm his already formulated views on the pathology of this affection, which are as follows (*Lancet*): Appendicitis is always the result of the conversion of the appendicular canal into a closed cavity, the closure taking place at any point in its length. Partial obliteration with resulting transformation into a closed sac is due to the progressive formation of a calculus more or less hard in consistence in proportion to the admixture in greater or less quantity of lime and magnesium salts to organic and stercoral ingredients. This calculus does not originate in the cæcum, but is the product of a true appendicular lithiasis comparable with biliary and renal lithiasis. The coexistence of these three lithiasis in the same family and their hereditary origin has often been remarked. Another cause of the obliteration of the appendix is local infection quite analogous with a similar obliteration of the bile duct in catarrhal icterus. In certain cases a fibrous stricture similar to an urethral stricture results in the shutting off of the appendix. The symptoms of mild or serious appendicitis reveal themselves only when the appendicular canal is converted into a closed sac; then the germs normally present in the appendix, inoffensive up to that time, multiply and become more virulent. Thus is constituted a highly dangerous focus of infection, the principal micro-organisms present being the coli bacillus and the streptococcus (a fact verified many times by Professor Dieulafoy and his interne, M. Kahn). The virulence of the appendicitis may of itself suffice to kill the patient while the peritoneal symptoms are quite subsidiary. In other instances the infection spreads to the peritoneum despite the absence of any perforation of the appendix; any variety of peritonitis may be developed (generalized, encysted, acute septicæmia, and peritoneal abscess *à distance*). Then, again, peritonitis may be set up by perforation. It would then appear that until the normal canal of the appendix is converted into a closed

cavity the symptoms of appendicitis are not present, and until this event has taken place we have no means of discovering the existence of a process which will infallibly result, some day, in an attack of that formidable disease.

Depilatories.—The ordinary components of the so-called depilatories, says *The Lancet*, are quicklime, soda, and a combination of sulphur and arsenic. The powder is made into a paste, spread on the face or other part, and washed off as soon as dry. It acts by desiccating and dissolving the hair shaft, and by reason of its irritating nature in unskilled hands is apt to give rise to troublesome consequences. Erasmus Wilson narrates the case of a young lady who had been making an experiment of this sort on her forehead for the purpose of getting rid of a tuft which interfered with the then fashionable mode of wearing the hair. She had unfortunately allowed the depilatory to remain on too long, and it resulted in a slough the size of a shilling, followed by an unsightly scar. The safest of such applications is a paste of barium sulphide and starch applied by skilled hands, regulated in strength to the delicacy of the skin. Kaposi mentions that in the Orient among the Jews a paste is used for the periodical removal of the stubble of the beard consisting of orpiment and slaked lime boiled with water. In this instance the aftergrowth does not appear until two or three weeks have elapsed, when the application has to be repeated. But all these methods are at best only palliative, for the formative organ remains, and they are all equally apt to be followed by a stronger growth of the hair, and sometimes they give rise to ugly marks and scars. Ointments have been employed, but in general are to be deprecated, for greasy applications tend to promote the growth of hair, as on the backs of the hands when vaseline is used to prevent chapping in cold weather. Nevertheless, a strong resorcin ointment, accompanied by powerful friction, has in the practice of a few found favor. The introduction of chromic acid and other caustics into the hair bulb by means of a needle is uncertain on account of the difficulty of regulating the resulting inflammation. The only efficient depilatory, the *Lancet* correctly adds, is the galvanic needle, a method devised by an American, Dr. Michel.

Operation for Hammer Toe.—We learn from an article published in the *Quarterly Medical Journal* that Dr. Péraire recognizes several varieties of hammer toe: (1) Hammer toe due to a vice of development of all the tissues of the toe; (2) hammer toe of arthritic origin; (3) hammer toe caused by a lesion of one of the constituent tissues of the toe; (4) hammer toe due to the wearing of too short boots. In his experience medical treatment of this condition has not been very successful. Orthopedic treatment in some cases gives good results after a time, but the condition often reappears under the influence of walking. Various operative measures have been suggested, viz., open or subcutaneous division of tendons, excision of a portion of the flexor or extensor tendon, amputation of the phalanx, disarticulation of the toe, and finally the procedure introduced by Professor Terrier, cuneiform osteotomy. The indications for this operation are: Ankylosis of the articulation between the two phalanges; presence of a corn or an inflamed serous bursa due to the friction of the boot over the projecting part of the toe; it is even indicated when there is pain in walking, more or less pronounced lameness or pain in the erect position. One ought more especially to have recourse to this operation when the patient not only walks upon the extremity of the nail but also upon the dorsal surface of the phalanx. He gives clinical histories of five cases, in all of which a good functional result was obtained.

The operation consists of five stages: 1. Excision of the soft parts over the projection formed by the articulation of the first and second phalanx. The corn is included in this incision, and the mucous bursa beneath the corn should be removed at the same time. 2. Opening of the joint by a dorsal incision, the extensor tendon and its sheath being cut at the same time along with the two lateral ligaments. 3. Clearing of the head of the lime. 4. Excision of the two articular ends by means of cutting-pliers. This is a most important part of the operation. Only sufficient of the bone should be removed to bring the toe in a straight line. 5. Adaptation of the two ends of the bones is made. The wound is sewed with silkworm gut, and drained or not. A small plantar wooden splint maintains the toe in a straight position. At the end of sixteen days the patient may walk. Péraire has used local anæsthesia by means of injections of cocaine and ethyl chloride.

Post-Influenzal Osteitis, Periosteitis, Arthritis, and Inflammations of Fasciæ.—Dr. Franke calls attention to a new form of infective inflammation which he has observed subsequent to attacks of influenza and of which he reports in detail twenty cases. The most frequent form, we learn from the *Annals of Surgery*, is an osteitis or osteoperiosteitis which may go on to suppuration or may produce simple local swelling and œdema and be followed by resolution. Like all the other manifestations, it can only be diagnosed by its proximity to an attack of influenza or by the presence of symptoms of that disease concurrently with it. When any of these inflammations resist all treatment and go on in a chronic course of latent character, the possibility of an etiology in influenza should not be overlooked and a history of a series of attacks or the presence of symptoms should tend to confirm the diagnosis. Osteoperiosteitis is the most frequent form, and under it may be classed, according to this author, the disease described by Albert as "achyllo-dynie," in which the insertion of the tendo Achillis is the seat of a periosteitis. The involvement of fascia is next in frequency, and chiefly an inflammation of the plantar fascia, whereby it becomes thickened without outward signs of inflammation: the thickening is usually along the inner border and at the insertions of the fascia. It is slightly sensitive to pressure and is painful to stand or walk upon for any length of time. Arthritis having as its sole cause an infection due to influenza is seldom seen, but does doubtless occur. The symptoms may manifest themselves three or four days after the inception of an influenza, but may be latent for even many weeks. The resistance to all treatment is very marked: the best results are derived from the applications of moist heat and massage, with incision and drainage in cases that go on to suppuration. The salicylates have been of no avail, as also all ointments and counterirritation, except, perhaps, in certain cases of ichthyol.

New Plastic Procedure in the Treatment of Unduly Projecting Auricles.—Dr. Haug excises an oval flap of skin from the fossa between the auricle and the mastoid process of the temporal bone (*Brooklyn Medical Journal*). This oval is then lengthened by incisions superiorly and inferiorly. To complete the operation the edges of the ovals are approximated by means of sutures. Should the cartilage of the auricle exert too great a resistance to the approximation of the edges of the oval a portion of it may be excised. Another procedure is to excise two portions of skin, one lying over the auricle and the other over the adjacent part of the skull. These are kept approximated by bandaging the auricle close to the head and then leaving it to heal in this position.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, March 14, 1896.

PURIFICATION OF DRINKING-WATER BY MEANS OF FILTRATION.

THE importance of pure water in determining the health of a community has long been recognized and cannot be overestimated.

At the present time it is impossible for many cities and large towns to obtain the required amount of water from a naturally pure source, and in the future, with the enormous increase in population and the number of manufacturing towns established along the banks of the small streams and rivers, this difficulty will be manifestly greater. Therefore the possibility of purifying by artificial means water which has been polluted by sewage and which contains both organic matter and bacteria, has become a question of great importance in many communities.

In considering any method for accomplishing this object two things must be borne in mind, viz., its efficiency and its cost. The objections which have been urged against filtration are:

First, that while a filter might remove the coarse material in suspension, it would allow all the organic matter in solution and the bacteria to pass through unchanged.

Second, that even if a filter were efficient for a short time, it soon becomes clogged and saturated, and then the condition of water which passes through is worse than when it entered.

Third, that the cost and maintenance of a properly constructed filter is so great that it cannot be universally adopted as a means of purifying water.

The report of the Massachusetts State Board of Health for the year 1894 contains some very interesting and important facts upon all these points.

For the past seven years the board has maintained an experimental station at Lawrence for the sole and express purpose of testing the efficacy of filtration of water to purify it and render it fit for household purposes. The water tested was that of the Merrimac River, which is lined from source to mouth with manufacturing towns and which may be taken as a fair sample of river water contaminated with a considerable amount of organic matter.

The filters were of all sizes and thicknesses, from those a few feet square and ten inches in depth to the large filter covering two and one-half acres, through which the water supplied to the city of Lawrence has been filtered since 1893.

Chemical and bacteriological examinations were made weekly and sometimes daily of the water of ingress and egress. Sand of different sizes was used, and the filters were run both intermittently and continuously.

The results of this careful and painstaking investigation, extending over a number of years and every source of error being eliminated, are both astonishing and gratifying.

From a bacteriological standpoint they prove that a properly constructed and properly managed filter will remove from 98 to 99.84 per cent. of the ordinary bacteria in water, and that if such bacteria as the bacillus prodigiosus, which is very similar to the typhoid bacillus, be added to the water in varying proportions, the filter will remove from 99 to 99.993 per cent. The organic matter in solution is greatly diminished and the water is chemically purified.

Moreover, the efficiency of the filter instead of diminishing increases with age and use, owing to the formation of a gelatinous coating about each grain of sand, which serves to entangle the bacteria in their progress.

The rate of filtration may reach five million gallons daily per acre of filter without impairing the efficiency. If the surface clogging is properly removed there will be no appreciable difference in the quality of the filtered water during or after the process of removal.

Finally, the cost of construction and maintenance of such filters is not so great as was supposed, and is not to be compared with the benefits derived from their use. The one which has been in successful use in the city of Lawrence proves that the plan is practicable in supplying cities with potable water. It seems to us that the knowledge derived from these experiments should be spread abroad and the attention of municipal authorities called to them.

In the immediate vicinity of New York the water of the Passaic River has been for a long time very bad and is constantly growing worse as regards its contamination with sewage and the waste of manufacturing plants on its banks. Several large cities and towns obtain their water supply from this source, and if there is a practical and economical means of rendering this water pure and wholesome it certainly ought to be adopted.

While our own Croton is considered a very good quality of water, yet it is liable to contamination, and we have recently had abundant proof that it may become disagreeable to sight and taste. A proper system of filtering would no doubt improve the quality greatly, and the matter should be brought to the attention of the proper authority.

The Clinical Recorder, of New York, edited by Dr. William S. Gottheil, M.D., is another candidate for favor. The first number shows much care in editing and contains articles by the following well-known writers: Drs. H. J. Garrigues, Carl Beck, S. Henry Dessau, Louis Fischer, William S. Gottheil, Augustin H. Goelet, Ferd. C. Valentine. The journal will be published quarterly.

THE AMERICAN LEPER.

IN view of the antiquity of leprosy and the richness of its literature, extending back into Biblical times, it surely is not creditable to medical science that such lack of knowledge still exists, not only as to the treatment of the disease, but likewise concerning the care of the individual sufferer.

At more or less frequent intervals a ripple of excitement is occasioned in the community by a newspaper account of how another leper has been discovered in Chinatown, or startling headlines announce how a case of true leprosy has wandered into a skin class at the dispensary. For a day the public is regaled with the profound views of various would-be authorities upon the subject. The reporter who is detailed to write the story takes down the batch of dusty documents from the office pigeonhole labelled "leprosy," selects his padding from such excerpts as contain references to the prevalence of the disease in Siberia, India, and Norway, puts in a word about the sad case of the martyr Damien, of Hawaii, but never gives enough attention to our own country to learn and tell how Father Boglioli, of New Orleans, contracted the disease in the discharge of his professional duties at the Charity Hospital in that city, nor how at the *Real Casa Hospital de San Lazaro* in that little island which is now so near to us, in more than one sense, a chaplain has met the same fate. Then the facile writer tells how fortunate this land of ours is to be comparatively safe from any fear of spread of the disease, refers to its gradual disappearance in Minnesota, quotes the English investigation committee and the chief inspector for contagious diseases of the health board to prove that it is not contagious, and ends with the information that the leper will be carefully isolated for the rest of his days in "the small wooden building of two rooms" on North Brother's Island.

New York City has just experienced one of these periodical thrills. Perhaps more than usual interest attaches to the last instance of the disease discovered in New York, because the patient is a native and has lived in this city for many years. He was born in New Orleans. For those, however, who are of an inquiring turn of mind and like statistics for their own sake, we might state on the authority of Dr. N. W. Blanc, who was for a long time connected with the institutions of Louisiana, that between the years 1885 and 1891 he found eighty-three cases of leprosy in the city of New Orleans. There a new case in a native occasions no comment. It is what they expect. It is only when a Chinese or Hawaiian leper enters the city that the papers take note of it.

Louisiana has gone to great expense in fitting up a beautiful leper home in the parish of Iberville, surrounded by gardens and woods and made in every way attractive, but at last accounts (see RECORD of March 16, 1895) the State authorities were meeting with difficulties in filling the institution—not for lack of subjects, but because lepers, in common with other mortals, love perfect freedom.

Our own facilities for taking care of this class of

patients are notoriously inadequate. The presence of lepers in the community causes too much talk. Louisiana naturally wants to fill her new hospital. The patients on North Brother's Island can by no possibility desire to remain in the care of the board of health. What solution of the problem as it affects this city can be more simple?

Nothing can be hoped from national control. Legislators are not going to trouble themselves about American leprosy so long as there are Armenian, Siberian, and Cuban affairs to be regulated. Even the public, down whose spinal column runs such a chilly stream at each new arrest of a leper in our streets, can scarcely be enlisted in any movement having for its object the care of lepers at home, but contributions scarcely have to be asked for when a Miss Marsden is to be sent to Yakutsk to found a Siberian leper colony.

The leper would seem possessed of greater attractions the farther away he is. Accounts of the hospital in Caracas, of the thousands of subjects in Colombia, of the miserable beings on Robbin Island who beg the soldiers to shoot them down and thus end their deplorable condition—all these are read and talked of, and humane measures are devised, while little note is taken of the inhumanity of boxing up a poor Chinaman in a freight car and shipping him to the Pacific Coast, where the authorities promptly re-box him and ship him back again with little to eat and still less to drink. If leprosy is not contagious why cannot the unfortunate leper be left unmolested? If he is a menace to the community why cannot proper treatment be accorded him in all parts of the country? No plan short of federal control will ever do for the American leper what his importance makes a necessity.

 THE CLINICAL APPLICATION OF THE ROENTGEN RAYS.

THE March number of the *American Journal of the Medical Sciences* contains an article upon this subject by Drs. W. W. Keene, E. P. Davis, and Prof. W. F. Magie. Dr. Keene sums up his experience by saying that, since all the normal structures of the body except the bones are permeable to the rays, it is not very probable that with present methods we can learn much about them by skiagraphy. The bones, however, being opaque, deformities, injuries, and diseases may be more or less amenable to diagnosis by this method.

Skiagraphy will probably help in the differentiation of fractures and dislocations, in outlining exostoses and bony tumors. Foreign bodies can also be located by it, even glass being quite opaque. One advantage is that the hand or injured part can be skiagraphed without removing the dressings. Dr. Davis attempted to secure a skiagraph of the fœtus *in utero* in living women. The faint outline of the trunk of the fœtus could be recognized, but the head of the child was hidden by the mother's pelvis, so that no definite indication of its presence could be obtained. While the experiment failed to outline distinctly the skeleton of the fœtus, Dr. Davis thinks it may be of help in

locating the position of the child and that the method can be further developed. The presence, for example, of more than one fœtus may thereby be appreciated. A very good picture of a fœtal skull containing buckshot is shown. The skiagraph shows the position of the jaw and orbits and of the sutures, and gives a rather definite outline in some parts of the periphery of the skull. Photographs are given showing tuberculous disease of the elbow-joint, intercondyloid fracture of the humerus, a resected elbow, and a hand in which buckshot and a needle have been buried. There is also the skiagraph of an infant's body, which shows the outlines of the ribs and pelvis. Professor Magie gives some interesting information regarding the technique of the method. Altogether, the article shows that already some appreciable help in diagnosis can be obtained by the use of the newly discovered rays.

Mr. Sidney Rowland continues his series of articles upon the same subject, published in the *British Medical Journal*. In the last number he makes the statement that Professor Kinsing, of Hamburg, has also been successful in obtaining a picture of a fœtus *in utero*. He reports the case of a patient who was suffering from a pain in the thumb, which she said was due to the presence of part of a needle that she had run into her hand six months before. The skiagraph showed the presence of the needle perfectly. Mr. Rowland also photographed a foot, showing the presence of tuberculous disease.

A TAG FOR DOCTORS.

COL. R. FRENCH STONE, Surgeon-General of the Indiana National Guard, urges a plea in the *Journal of the American Medical Association* for the adoption of international medical insignia. Dr. Stone states that particular symbols have, in all ages, been assumed by the various families of the human race, and he thinks that in view of those facts physicians should have the privilege, in the exercise of their life-saving mission, of proclaiming to the world the nature of their vocation by means of some mystic heraldic emblem. After much thought and ingenious labor, Dr. Stone has devised an insignia, for which a patent has been applied for and which he presents for the approval and adoption of the profession. The design consists of a shield which has a gold border enclosing a dark-green central field, upon which is a modified red Maltese cross surrounded by a strip of gold. The red color of the cross and the green color of the field are, he says, not only universally recognized as symbols of life, but are also the most attractive and beautiful shades in nature. The shield is of the ancient triangular Egyptian type, in actual use as protective armor at the time when the healing art was first recognized as an independent vocation. The same insignia is presented in the form of a circular shield, and Dr. Stone states that these can be gotten up in either a simple or an expensive way, so that prices may range from twenty-five cents to many dollars.

We feel the greatest respect for Colonel Stone's

heraldic knowledge and for the industry and good taste which he has shown in working out his breast-pin. But we protest that the medical profession does not need a tag to advertise itself. A doctor nowadays no longer belongs to a mystic cult or to a peculiar and isolated calling which sets him apart from the rest of his fellow-men. He is simply a man like other men, except that he has had a special education and special training in the science of disease and in the art of treating it. We are sorry to see so much fine scholarship as Dr. Stone has shown thrown away. Perhaps, however, he can utilize his investigations and his patented insignia for some special association of physicians. There is no reason why doctors, like other men, should not organize into mystic or non-mystic corporations and adorn themselves with all the uniforms and buttons, breastplates and insignia they wish.

A HOMICIDE EVERY TWO HOURS.

A CORRESPONDENT of *The Lancet*, writing from Rome, gives an account of an address of Prof. Baron Garofalo delivered recently before a popular audience in that city. Garofalo, who is recognized as one of the leading penologists of Italy, gave some statistics regarding the annual loss of life by homicide in Italy which were very startling. The total number of murders in Italy, during the last year, was about 4,000, which is equivalent, said the speaker, to a homicide every two hours. This a very much greater mortality rate than exists in other civilized countries, the ratio in France being one-tenth that in Italy and the ratio in Denmark being one-thirty-fifth of that in Italy. This tendency to homicide is due, according to Baron Garofalo, first, to the existence of the vendetta, which has lingered longer in Italy than in any other country; then, to the practice of duelling, and, perhaps more than all, to certain defects in education and to racial tendencies. Garofalo thinks that the remedy for this consists in improving the system of administration of justice, in enforcing capital punishment, in recasting the methods of education throughout Italy largely on the lines advocated by Lombroso and his school, and, finally, in the ennobling of the moral and religious sentiments of the people. This, according to Garofalo, is to be done not so much by moral as by religious inculcation. To the religious instruction given in Great Britain and in the United States he attributes the fact that these countries have in forty years diminished by one-half their annual proportion of delinquents and mendicants, while in Italy there has been an increase in both delinquency and mendicancy since 1862. Baron Garofalo's strong advocacy of the value of religious training, coming, as it does, from a pupil of the school of Lombroso, is a factor which religious teachers and professors in this country will rejoice over with great heartiness.

Adoption of the Bertillon System.—The police board of this city has formally adopted the Bertillon system for the identification of criminals.

News of the Week.

Liability for Damages in Making Unauthorized Autopsies.—Justice Patterson of the Supreme Court of this State has ruled in a recent case, in which an autopsy was made by one of the surgeons of Bellevue Hospital against the wishes of the relatives of the deceased, that a suit for damages can be instituted. He maintains that such a complaint establishes an unlawful act on the part of the defendant; although the criminal law does not give or recognize a civil suit for damages, unauthorized dissection is made a misdemeanor by the Penal Code, and the chapter prohibits dissection or delivery of a dead body for that purpose against the objections of relatives or friends, if they apply for the remains for the purpose of burial within a certain time. He further continues: "The right is to the possession of the corpse in the same condition it was in when death supervened. It is the right to what remains when the breath leaves the body, and not to such a hacked, hewed, and mutilated corpse as some stranger, an offender against the criminal law, may choose to turn over to an afflicted relative. If this right exists, as we think it clearly does, the invasion or violation of it furnishes ground for a civil action for damages. A right to vote can in no sense be called a pure right of property; it is merely a personal right; yet who would now contend that a person obstructing a voter's right or preventing his voting would not be, irrespective of any statutory enactment, liable, even if the candidate of the choice of the person thus obstructed was elected?"

The New St. Luke's Hospital will, on April 16th, formally open its general wards for the reception of patients. The private-room service has been in operation for three weeks past. The first blood in the operating-theatre was from an appendectomy performed by Dr. Abbe.

A Bill to Create Lay Ophthalmologists.—We commend to the attention of our readers the following circular issued by the committee on legislation of the Medical Society of the State of New York:

"To the Medical Profession of the State of New York:

"A bill has been introduced in the Assembly incorporating the Optical Society of the State of New York, the passage of which would be a serious menace to the public at large and an infringement on the laws governing medical practice.

"This bill gives to the New York Optical Society, which is not composed of medical men, the exclusive right to issue certificates to opticians, charging for each the sum of twenty-five dollars; certificates which it can revoke at its pleasure. It also has the power to license 'refracting opticians,' thus putting in the hands of incompetent people the right to fit glasses for various troubles of the eyes, privileges which should be only in the hands of competent physicians.

"A bill was hurried through the legislature during the last session which conferred on chiropodists medical rights, the possession of which, in the hands of the ignorant, cannot fail to work harm to the commu-

nity. It is our duty as physicians and guardians of the public health to keep a watch on these efforts to evade the laws governing medical practice and to enter at once a vigorous protest.

"The members of the legislature are in nearly every instance willing to be guided in these matters by the expressed desires of the medical profession; it is therefore requested that every physician throughout the State write to the senator and assemblyman representing his district, protesting against this bill and requesting the representative to use his influence to defeat it.

"The bill is entitled 'An Act to Incorporate the Optical Society of the State of New York,' etc., and is known as Assembly Bill No. 727, which number please use in writing to your representative.

"A. WALTER SUITER, M.D.,

"MAURICE J. LEWIS, M.D.,

"J. M. WINFIELD, M.D.,

"Committee on Legislation."

We trust that every practitioner in the State will do his best to defeat this unjust and outrageous measure.

Obituary Notes.—DR. ELIHU VEDDER died at his residence in Jacksonville, Fla., March 9th, aged ninety-four. He was born in Schenectady, N. Y. He practised dentistry in Cuba for thirty years. He was the father of Elihu Vedder, the artist.—DR. WILLIAM H. STEWART, of Philadelphia, died on March 3d at Asheville, N. C., at the age of thirty-five years. He was graduated from the University of Pennsylvania in the year 1882, served a term as resident physician in the Philadelphia Hospital, and was for a year surgeon on board the American line steamship *Ohio*.—DR. IRVING WHITALL LYON, president of the Hartford County Medical Society, died at Hartford, Conn., March 4th, from pneumonia, after an illness of only two days. He was a graduate of the Vermont Medical College and of the College of Physicians and Surgeons in this city, serving afterward for two years in Bellevue Hospital. He settled in Hartford in 1866. He was buried at Bedford in New York State.

Advertisements are not Original Articles. It is always a pleasant recognition of merit to be quoted in our exchanges and we appreciate the compliment accordingly. We strenuously object, however, to the quotation of an advertisement as if it were original reading-matter appearing in our columns. A flagrant instance of the latter practice has been brought to our notice, in which a prominent firm asks in a circular letter that the medical journals of the country insert as a "reading notice" that the MEDICAL RECORD has published as an original article what was really one of its advertisements, paid for at regular rates. We hold that this is a very unfair proceeding to all advertising patrons and general readers, and respectfully ask that no medical journals be parties to such misrepresentation.

Gifts to a Hospital.—Lord Mount-Stephen and Sir Donald Smith have each contributed \$10,000 to meet the current expenses of the Royal Victoria Hospital, Montreal, which they erected at a cost of \$1,000,000 and afterward richly endowed.

No Civil-Service Rules for Attending Physicians.—Civil-service rules cannot be made to apply to the positions within the gift of the Commissioners of Charities. In denying the application for a peremptory writ of mandamus to compel the physicians connected with the various city institutions to undergo examination, Judge Andrews says: "The visiting and consulting physicians and surgeons are neither officers nor employees within the meaning of the civil-service acts. They receive no compensation; their positions, so far as pecuniary benefit is concerned, are purely honorary, and it is inconceivable to me that the legislature should have intended that the most eminent members of the medical profession should be subjected to the indignity of an examination, either competitive or non-competitive."

The "X" Rays in Surgery.—A successful conjoint demonstration of the clinical uses of Roentgen's rays was made by Dr. E. P. Davis, Prof. W. F. Magie, of Princeton, and Dr. W. W. Keen, of Philadelphia. A number of interesting negatives were shown; for instance, of a tuberculous abscess of the elbow-joint, of ankylosis of most of the bones of the fingers of one hand in consequence of a burn, of a bullet lodged in the forearm for eighteen years, of an excision of the elbow with the parts supported by an iron splint and a plaster cast and surrounded by the usual dressings; some of the patients were shown also. A shadow-picture ("skotograph" or "skiagraph") was made at the meeting, showing fracture of both bones of the forearm in a young man with a resulting lesion of the nerves and palsy and loss of sensibility in the hand. Professor Magie, who spoke of the physics of the subject, inclined to the view that the new force was transmitted through longitudinal vibrations of the ether in contradistinction to the transverse waves through which ordinary light is transmitted. He showed an instrument that he had devised and named a skiascope, which consisted of a cylindrical tube surrounded by black paper treated with platino-barium cyanide and which, held before the Roentgen light, makes possible the direct observation of bodies interposed. Dr. Davis stated that he had succeeded in photographing parts of the fœtus in utero prior to descent into the pelvis behind the bony parts. The eye both of the fœtus and of lower animals intercepted the light and thus appeared opaque. Among other things it was hoped that living and dead tissue would react differently to the light and that we might thus have a certain test for death, but the results proved the hope illusory.

New York's Molokai.—Leper number five has been added to the colony on North Brother's Island in the person of Joseph Cummings, who for eighteen months has been going about in this city with well-marked evidences of the disease. The patient just admitted is fifty-four years of age and has lived in New York since 1879. He was born in New Orleans, where considerable leprosy has existed for many years.

Jefferson Medical College.—The board of trustees of Jefferson Medical College has at last filled the

chair of pathology and bacteriology in that institution, which has been vacant for two years, by the election of W. M. Late Coplin, a graduate and former lecturer on pathology in the Jefferson School. Dr. Coplin left Jefferson less than a year ago to accept the chair of pathology and bacteriology in Vanderbilt University at Nashville, Tenn.

The Pennsylvania Epileptic Hospital and the Colony Farm for Epileptics have been consolidated under the title of the Pennsylvania Epileptic Hospital and Colony Farm. Both institutions will be continued, patients being transferred from the one to the other as occasion requires.

Medical Department of the University of Buffalo.—The medical department of the University of Buffalo announces that it has adopted a four years' course, beginning with the session of 1896-97.

Death of Hiram Corson, M.D.—The name of Hiram Corson, who died at his home at Plymouth Meeting on March 4th at the ripe age of ninety-two years, will always occupy a conspicuous place in the medical annals of the State of Pennsylvania. Dr. Corson led an active and useful life in the sixty-seven years' practice of his profession and was a generous contributor to current medical literature. He was an earnest advocate of the use of ice in the treatment of scarlet fever and diphtheria and of bleeding in pneumonia, and was opposed to the use of alcohol in conditions of both health and disease. He was graduated from the University of Pennsylvania in 1828 and resided all of his life in Montgomery County. He occupied numerous positions of trust and was honored with membership in many learned societies.

The Altoona Academy of Medicine and Surgery gave a banquet on March 3d in honor of its guest, Dr. John B. Roberts, of Philadelphia.

Official Carbolic Acid.—At the meeting of the Philadelphia College of Physicians on March 4th Dr. Oscar H. Allis read a paper entitled "The Surgical Uses of Official Carbolic Acid," in which he pointed out that while toxic effects may and often do follow the use of dilute solutions of carbolic acid by topical applications or for purposes of irrigation, the deliquescent acid could be used without deleterious effects and with especially good effects if applied to fresh wounds and to burns. The weak solution is readily absorbed and thus exerts its toxic effects, while the strong acid coagulates the albumin of the tissues, renders the nerves anæsthetic, and closes tightly the blood-vessels and lymphatics.

Regulating the Practice of Horseshoeing.—A bill is before the legislature at Albany, providing that blacksmiths must pass an examination and receive a regular license before they can be allowed to follow their art. The bill is supported by the Society for the Prevention of Cruelty to Animals, the members of which argue that, since the practice of medicine is regulated, together with the practice of dentistry and the veterinary practice, blacksmithing should be reg-

ulated. As time goes on and the process of regulating things continues, we trust that there will be a regulation in the practice of publishing newspapers and of putting before public notice foolish ideas. The practice of philanthropy might also become gradually regulated, so that no person could be either an amateur or a professional philanthropist unless he passed an examination showing his attainment in economics, ethics, and common sense. The regulation by the State of the practice of different things holds up to the imagination some most delightful prospects of improvements in our present imperfect social fabric. For our part, however, after the blacksmith has been regulated and horseshoeing is done only by professional men who have a proper pride in their art and a well-defined code of ethics, we trust that the regulation of philanthropy will be next and seriously undertaken.

Abortive Treatment of Typhoid.—There has developed in the West a form of treatment for typhoid fever which is known as the "Woodbridge abortive method." This has been much exploited in the medical press, and we have ourselves given a faithful account of it. We have expressed doubt as to the results of the method and do not consider that its efficacy has been satisfactorily proved. Nevertheless, the originator of the method has secured such a reputation that he has moved to Cleveland, O., for convenience in responding to consultation calls.

Antistreptococcic Serum in Scarlet Fever.—Dr. Marmorek, writing in the *Berliner Medicinische Wochenschrift*, has given an account of the treatment of scarlet fever with antistreptococcic serum. Although the micro-organism of scarlet fever has not yet been discovered, the relation of streptococci to scarlet fever is of great importance, for their presence in the numerous sequela of this disease, such as abscesses, nephritis, and endocarditis, shows the danger of such a combined infection. From October 16th up to the end of December, 1895, Dr. Marmorek had under his care 103 children affected with scarlet fever, and 96 of them were treated by injections of serum, the total quantity of which amounted to 30,000 units. In 7 cases which were admitted in a state of total exhaustion no injection was performed. Of 17 cases in which Loeffler's bacilli also were found, 4 died in spite of the injection of both diphtheria antitoxin and antistreptococcic serum. In slight cases 30 c.c. of serum were injected, in urgent cases 40 c.c., 60 c.c., and 70 c.c.; 90 c.c. were injected in a case complicated with broncho-pneumonia. The most remarkable effect was the decrease of the swelling of the lymphatic glands. Albuminuria was sometimes observed two days after the injection. The pulse became slow and strong and the exudation in the pharynx was cast off.

The Kansas State Medical Society meets in May and its secretary sends out the following seductive circular to the doctors of the State: "The next meeting of the Kansas Medical Society will be held at Topeka, on May 13, 14, and 15, 1896. If we missed your smiling countenance last year, it was because

you were too busy to come. You don't know what you missed! If you don't attend this year, you'll miss the greatest meeting in the history of this society. There are no personal 'scraps' on hand for this meeting, but we expect to have the judicial council present so you can submit your personal grievances to them. If your collections have been bad during the year, make a 'kick'—they'll enjoy it. So prominent has the society become that it is with great difficulty that we can keep away the prominent men from Chicago and Kansas City. How blood will tell! They enjoy coming to Calamity Kansas and meeting their peers. This year we succeeded in keeping all but three or four outside the borders of Kansas. Among those who will be with us is Prof. N. Senn, of Chicago, who comes on one condition only, viz., that every member of the society attends. We expect by May to have the Gothemburg system in vogue, so you can take refreshments in the basement of the Capitol—if you carry your bottle along. No one will say a word if you're not seen. If collections improve, I think we can prevail upon the good doctors of Topeka (not even excepting those who lately got 'mixed up' with the 'dead') to give you a banquet on the evening of May 14th. There is one condition about attending this banquet, and that is that you spend at least one day at the society. No ringers allowed. Come one, come all!"

A Hard Case.—*Le Scalpel*, a very ably edited Belgian medical journal now in its forty-ninth year, relates the following case as a warning to surgeons against *trop de zèle*. A practitioner of Brussels had a patient who was suffering from a uterine affection. A specialist having been consulted, curettage was recommended and agreed to by both the woman and her husband. She accordingly entered an institution in order to undergo the operation, but while it was in progress the surgeon became aware, after dilatation of the cervix uteri, that he had to do with carcinoma. The patient being under the influence of an anæsthetic and the husband absent, their consent could not be obtained; but the operator nevertheless decided to perform hysterectomy on his own responsibility. All at first went well, but unfortunately the woman died subsequently from hemorrhage, whereupon the husband sued the practitioner, claiming damages to the extent of 50,000 francs for the loss of his wife. The Ministry of Justice came to the conclusion that 5,000 francs would suffice; but at the time of writing judgment had not yet been pronounced. The case points to the inadvisability of performing such an operation as hysterectomy without the consent of the patient and her husband having been previously obtained. In the above case there is no reason why the operator, having ascertained the nature of the disease after dilatation of the cervix, should not have waited a few days before proceeding to remove the uterus.—*Lancet*.

The Twelfth International Medical Congress.—The arrangements for the next International Congress, which will be held in Moscow in August, 1897, are now being worked out by the special committee appointed for the purpose. There will be twelve sec-

tions, as follows: (1) anatomy, (2) physiology, (3) general pathology and pathological anatomy, (4) general therapeutics, (5) internal diseases, (6) children's diseases, (7) nervous and mental diseases, (8) dermatology, (9) surgery and diseases of the eye, (10) midwifery and gynecology, (11) hygiene, and (12) legal medicine. The government has assigned 35,000 roubles for the expenses of the congress. The official language of the congress will be the French language, but in the general meetings, of which there will be three, communications may be made in any European tongue. In the sectional meetings only three languages will be admitted—namely, French, German, and Russian. It will be seen that in this respect the organizing committee has altered its original intentions, which were to make French and German the official languages and to exclude all others completely. The propriety of admitting Russian communications to a congress held in the Russian capital cannot be questioned. Englishmen, however, must still regret that they will be debarred from making communications in their own tongue to the sectional meetings and that their only opportunity of reading papers in the English language will be in the three general meetings.

French Congress of Alienists and Neurologists.—

The Seventh French Congress of Alienists and Neurologists will hold its opening meeting at Nancy on August 1st. The questions proposed for discussion are: 1, The Pathogeny and Pathological Physiology of Hallucinations of Hearing; 2, Symptomatology of Tremors; 3, The Confinement of Lunatics in Special Institutions; Treatment and Legislation.

Antitoxin Gems.—A certain much interleaved medical journal published in the West punctuates its valuable space with items regarding antitoxin and serum-therapy which afford rich food for reflection upon the pathological idiosyncrasies of the human mind. Here are some samples: "'Pirates in Paris.' Physicians in Paris who prescribe animal serum are called 'pirates.'" "Under the head of the question of 'poisoning,' the MEDICAL RECORD reports a case of poisoning due to stale eggs. Many cases of poisoning, due to stale antitoxin have been reported, but these latter are only scientific experiments." Again: "Will some bright and progressive American doctor prepare antitoxin for the cure of asininity, now prevailing to an alarming extent across the pond?" To this we should say that there is not at present enough for local consumption in areas watered by a certain great river.

Massive Injections of Serum.—M. Lejars reports some extraordinary cases illustrating the value of intravenous injections of aseptic serum at blood temperature and in massive doses, that is, two pints three times a day. These injections, he says, are innocuous and they are capable of bringing about most unhopèd-for cures in certain cases, especially those involving the peritoneum. He thinks they act by provoking large evacuations of the toxins of the blood through the kidneys. M. Lejars describes a

remarkable case of peritonitis due to rupture of the intestine, in which after laparotomy the patient received in the course of nine days forty-five pints of artificial serum. The Paris correspondent of the *Medical Press* translates the author's description of the details of his mode of treatment: "Our method of operating," he says, "is very simple. We use a glass recipient properly sterilized and a glass cannula with a fine point; the vein is dissected through a small incision, tied, and opened with every antiseptic precaution above the ligature, and the cannula introduced, care being taken not to let in a bubble of air. By raising the recipient the liquid enters by its own weight; a certain thrill felt by the finger indicates that the solution is penetrating. At the end of the operation the vein is tied above the wound and the skin brought together by two sutures. At the second injection a segment immediately superior of the same vein is opened or one of the neighboring veins. In proceeding thus by segments from below upward from the bend of the elbow to the shoulder, on the superficial veins, quite a series of injections can be made, clots being entirely exceptional. In the case above related in detail more than twenty injections had been made in both arms. It might be possible to pierce the vessel directly with the point of the cannula if it were standing out in bold relief, but it must be remembered that the cases where these injections are useful the veins are frequently flaccid. Out of fifty intravenous injections we never observed the slightest accident, nor have we remarked that the operation was painful. Sometimes, however, we observed a little dyspnea at the end of the injection. The patients feel the liquid penetrating, they experience at first an irritation of the tongue and mouth, then a difficulty in breathing, and finally a sharp abdominal pain of short duration, all these sensations proving that the liquid was being rapidly diffused. As to the liquid, the useful formula of Professor Hayem will answer every purpose:

R Chloride of sodium (pure)..... 3 i.
Sulphate of sodium..... 3 ij.
Distilled water..... 1¾ pints.

The question of intravenous injections as applied to certain diseases is still on its trial, but in my opinion we have here a therapeutic method of considerable value in the great struggle with death."

A Doctors' Building in Philadelphia.—The proposition discussed from time to time as to the erection in Philadelphia of a large building devoted to the professional purposes of reputable physicians and dentists, such as exists in other large cities, e.g., Chicago, Denver, Pittsburg, is finally taking material shape. An organization has been effected and plans have been prepared for the erection of a handsome, suitably equipped, ten-story fireproof building at Eighteenth and Chestnut Streets, upon which it is hoped to begin work with the opening of the building season.

Dr. Robert Ellis Swan, a well-known physician and pharmacist and a nephew of the noted London pediatricist of the same name, died on February 24th at the age of fifty-six years.

Pennsylvania Colony for Epileptics.—The need of institutions for the care and employment of epileptics has long been recognized. The first known attempt in this direction was made in France in the middle of the present century and the colony then established at Lyons is said to be still in active and successful operation. Some twenty years later the colony at Bielefeld was founded. In the United States the agitation has resulted in the establishment of colonies, or in the institution of the necessary preliminary measures, in the States of Ohio, New York, Massachusetts, and Maryland, and now Pennsylvania has fallen into line. Several months ago an organization of prominent laymen and physicians was formed for the purpose of establishing a Pennsylvania Colony Home for Epileptics and Dr. Wharton Sinkler, who has taken much interest in the matter, was elected president. For the purposes of this colony home a farm of one hundred and ten acres at Oakbourne, Chester County, has been purchased; plans and specifications for the erection of suitable buildings, etc., are in course of preparation, and it is hoped that the work of construction will begin early in coming June.

Bluffing to the Last.—The business manager of a certain much-advertised consumption cure recently died from tuberculosis.

Orchotomy for Enlarged Prostate.—Dr. Mansell Moullin expresses an opinion in favor of orchotomy for enlarged prostate in old men. His experience is limited to twelve cases; of these twelve two died shortly after the operation, one from fatty degeneration of the heart, the other from apoplexy; two others died about six months after the operation; two more had suffered from traumatic delirium. In all the patients who lived there was a distinct amelioration of the symptoms. Dr. Moullin, however, thinks that perhaps unilateral orchotomy, or even resection of the vasa deferentia, may be followed by good results.

Pathological Society of Philadelphia.—At the meeting of the Pathological Society of Philadelphia on February 27th, Dr. Herbert U. Williams, of Buffalo, presented an exceedingly interesting and unique specimen obtained from a man of mature years, consisting of a duplication of the aorta from a point just beyond the origin of the left subclavian from the arch to the division into the two iliacs, each of which arose from a different vessel. There was a good deal of discussion as to whether the condition were a congenitally bifid aorta or an enormous dissecting aneurism, the preponderance of opinion favoring the latter view.

Americans as Champagne Drinkers.—In the year 1895 there were imported into America 2,878,140 bottles of champagne.

Philadelphia County Medical Society.—At the meeting of the Philadelphia County Medical Society on the evening of February 26th, Dr. F. P. Henry presented specimens of embryo filaria sanguinis hominis nocturna obtained from the blood of a case of endemic filariasis—the first it is said that has been

observed in Philadelphia. The patient was a woman, twenty-nine years old, who had never been out of the United States, having lived for twenty-seven years in South Carolina, for one year in Florida, and one year in Philadelphia. In the discussion it was pointed out that the presence of the parasite in the superficial vessels might be related to the periods of activity of the host rather than to the time of day, and that not uncommonly in cases of chyluria and lymph-scrotum either mature or embryonic filariæ cannot be discovered.

The Healthfulness of the Different Parts of New York.—In a report of the New York State Board of Health showing the mortality rate for the different diseases in different sanitary districts we find that the total death rate per thousand is highest in the maritime district (New York, Brooklyn, etc.), it being there 21.20; in the west-central district it is 13.40 per thousand; in the Adirondack and northern district 13 per thousand, and it is lowest along the southern tier of counties, where it is only 12 per thousand. The mortality from zymotic disease is highest in the Lake Ontario and western district, being there 308.31 to each thousand deaths, and lowest in the Adirondack region. In this latter region, however, deaths from consumption are higher than anywhere else in the State, being 114.50 per thousand deaths. Typhoid fever seems to prevail least of all in the maritime district, 7.06 per thousand, and most of all in the Hudson Valley, where it is 33 per thousand.

The Insane of London now number 13,047, and the County Council expects to have to provide for 600 more patients every year.

Cremation in America.—Of the 1,566 bodies that have been cremated at Fresh Pond in this State more than one-half, that is to say 820, were born in Germany and only 15 were born in Ireland.

Carrying Children on Bicycles.—San Francisco has passed an ordinance prohibiting bicyclists from carrying on their machines any child under the age of six years.

The Post-Graduate Hospital has adopted a regulation prohibiting the use of chloroform as an anæsthetic without consultation and directing that the reasons for the choice of an anæsthetic be recorded in the history of the patient.

The First Number of the Journal of Experimental Medicine, edited by Dr. William H. Welch and published by D. Appleton & Co., of this city, has just appeared. The first volume contains two hundred and one pages and seven original articles. Among them is one by Drs. William H. Welch and Simon Flexner, upon the "*Bacillus Aerogenes Capsulatus*," which is not concluded; one by Dr. William T. Porter on the "*Closure of the Coronary Arteries*," and also pathological articles by Drs. T. E. Shields and Ludwig Hektoen, these latter being illustrated with several excellent plates. The only articles which may be considered strictly practical is the one on the "*Production of Diphtheria Toxin*," by Drs. W. H. Park and A. W. Williams. All the contributions are

the results of original work carried out in a scientific spirit. The typography of the journal is excellent, and the new venture promises to be a credit to American medicine.

Paris too Popular as a Medical Centre.—French medical students complain that they are crowded out of their own schools by foreigners. The foreigners cannot be very largely made up of Americans, since the American student generally goes straight to Germany. At the Sorbonne there are but twenty Americans as against two hundred at the University of Berlin alone. Paris has not regained its prestige as a medical centre and does not in any wise deserve it. Much more thorough work and much more of the true scientific spirit can be imbibed in the German universities, to say nothing of the fact that until within two months the difficulties in the way of following courses and securing degrees were much greater in Paris. If these plain words will help to lessen the crowd of foreigners around the French medical students they are welcome to them.

Anti-Typhoid Serum.—The attempt to treat typhoid fever by immunizing serum obtained in various ways has, so far, been unsuccessful. At a recent meeting of the Paris Société de Biologie M. Chantemesse said that he had succeeded in immunizing horses against the virus of typhoid fever, and had obtained an immunizing serum which prevented the development of typhoid in the guinea-pig. He has employed injections of this serum in three cases of typhoid fever. The temperature showed a regular fall, and seven days after the commencement of the injections all three patients were free from fever and had commenced to convalesce.

The New York Medical Profession includes among its members a gentleman who is fast acquiring distinction in the literary world. Dr. E. C. Savidge has done a good deal of literary work of various kinds and has recently published a novel called "The American in Paris," which is eulogized very highly by the *Book News*.

The Office Thief is still busy in this city and physicians who are anxious to save their overcoats, instruments, and so on, should be on the lookout.

The Source of the Blood Plate.—According to Dr. Liten, of Berlin, the blood plates are not the decomposition products of white blood cells, nor preparatory stages of red blood cells, but are the decomposition products of the red blood cells. They are the stroma of the red cells minus the hæmoglobin.

Measles is unusually prevalent in this city at present.

An Effort to Legalize the Keeley Cure.—Mr. C. Smith has introduced a bill in the New York legislature providing that every person after having been twice committed for drunkenness shall be compelled to take the Keeley cure. This utterly absurd proposition is not only an unconstitutional interference with personal liberty, an impudent endeavor to legalize and encourage the work of a private corporation to the ex-

clusion of other methods, but is an insult to the medical profession of this State.

Obituary.

LAUGHLIN MCFARLANE, M.D.,

TORONTO, ONT.

DR. LAUGHLIN MCFARLANE, professor of clinical surgery in the University of Toronto, died February 29th, aged fifty-six.

"Peace hath her victories no less renowned than war." Peace has also her heroes and her sacrifices as noble as any that are demanded on the field of battle. Dr. McFarlane lost his life in the performance of his duty as a surgeon. A week before his death he was called to remove a patient's frost-bitten toes which had become gangrenous. In applying the sutures after the amputation he pricked one of his fingers with the needle. After taking the usual means of prevention in such cases the matter was not thought of again until the following day, when he had a slight pain in the finger, followed in a few hours by alarming symptoms indicating that blood poisoning of a most pronounced type was present. The symptoms were at first somewhat relieved by free incisions, but in a day or two the whole arm became swollen and there was marked evidence that the poison had fastened itself by this time on the entire system. The patient rapidly passed into a delirium that was succeeded by coma ending in death.

Dr. McFarlane was a Canadian by birth and belonged to a hardy race of Scotch-Canadians. He was possessed of those attributes of character with which success in life is almost guaranteed. He graduated in medicine at Toronto University in 1867 and at once located in the city where his life work will long be held in loving memory. Early in his career he became a member of the medical faculty of the university and later on a member of the senate of that institution. For his position as professor of clinical surgery he was peculiarly well qualified and his contributions to surgical literature bore evidence of his skill and erudition. He was an honored and valued member of several medical associations. The president of the Ontario Medical Association in his annual address last June referred to the fact that each year it became a painful duty to allude to the death of some past president. Dr. McFarlane, as a past president of the association, in moving a vote of thanks for the address, alluded in feeling and eloquent terms to those who had been honored by the association and are no more. Little did any who were present that day and heard Dr. McFarlane, looking the very picture of health, think that at the next meeting the members of the Ontario Medical Association would sigh

"For the touch of a vanished hand
And for the sound of a voice that is still."

Dr. McFarlane was an energetic and indefatigable worker in his profession, and ever ready for any sacrifice necessary in the interests of the University of Toronto. Although his professional connection was among the very best people in Toronto, his kindness of heart was manifested during his honored career in loving service for the poor, whose friend he was at all times. His funeral, March 2d, was one of the largest ever seen in Toronto and was a fitting tribute to the memory of one whose life had been nobly spent and whose death was a heroic termination of an existence replete with good works. The genial, kindly greeting of Dr. McFarlane at all meetings of Canadian medical associations will long be affectionately remembered.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CHRONIC CANCER—RUPTURED SPLEEN—SPLENECTOMY—PNEUMOTHORAX—ARMY REPORTS—REGISTRAR-GENERAL'S REPORT—THE NEW PHOTOGRAPHY—DR. RUFFER—SMALL-POX—DEATH OF ANOTHER VETERAN ARMY SURGEON—THE PARASITE OF MALARIA—SPECIAL DEBATE AT THE MEDICO-CHIRURGICAL SOCIETY MEETING.

LONDON, February 27, 1896.

THE interest attaching to the various questions in relation to cancer never seems to flag although it may shift a little as to the point of view. Lately the Liverpool Medical Society, considering the uncertainty of our information as to operative procedures, determined to ask the several hospitals in the town to furnish their complete statistics to a committee of the society to examine and report upon. I hope the authorities of the several hospitals will hasten to give the information they possess and that the committee may be able to extract something from the statistics.

Another aspect of this subject came up in the Clinical Society of London last Friday, when Mr. Nunn gave a further account of a case, previously reported, of cancer of the breast which has now continued for more than thirty years. The woman became an out-patient of the Middlesex Hospital in June, 1862, when she was thirty-seven years old.

There was then a scirrhus tumor of the right breast, which Mr. Nunn removed. There was also a chain of enlarged glands in the axilla. In 1866 pain was complained of in the muscles of the arm and fingers. In 1868 the patient was no worse. In 1878 there was a very limited return at the upper border of the cicatrix. In 1893 there were increased deposits and the arm was swollen. The swelling subsided and the patient ceased attending the hospital. In 1895 Mr. Nunn found she was still alive and working as a charwoman.

Mr. Nunn also communicated the sequel of another case recorded by him in 1878. That patient died a year later and secondary deposits were found post mortem in the liver and lungs. Drawings and slides were exhibited. Mr. Nunn also referred to the recurrent tumor removed and exhibited by him before the Pathological Society in 1880, the original tumor having been removed by Mr. Curling seven years previously. A second recurrence occurred in 1882 and the tumor was removed by Mr. Lawson; the patient was lately seen alive. Mr. Howard Marsh mentioned the case of a lady, now seventy-one, who had had cancer for eighteen years and on whom he performed lately the tenth operation she had undergone. When first operated on there was nothing to indicate that the course would be so unusual, and Mr. Marsh remarked that these cases disposed of the statement often made, that where recurrence did not appear for three years a patient might be considered cured. These cases prove the contrary.

Some cases of splenectomy were related at the same meeting. The operations were performed for rupture and it was suggested that the subsequent histories would be interesting, as we do not know much about the after-effects of removal of the spleen in healthy persons—less indeed than in leukemia. Several of the surgeons present made observations as to the operative procedure. Two cases of pneumothorax in the course of typhoid fever, both due to straining at stool, were related by Dr. H. White. One of the patients improved for three days but then died; the other completely recovered. The first had pleurisy and the fluid

was withdrawn. The second had a localized empyema and after he rallied foul purulent fluid was withdrawn. It was conjectured that in the first case the pleura, weakened by inflammation, ruptured during the straining, and in the other that the localized empyema burst into the general pleural cavity under the same pressure, and so the pneumothorax was established in each case. Dr. Goodhart read notes of a rather singular case of pneumothorax without obvious cause occurring on the right side, recovery taking place and a year later the same condition ensuing on the opposite side, again without obvious adequate cause and again the air being rapidly absorbed without any sign of pleurisy. He thought the rupture of an emphysematous bleb the most probable explanation. Some cases were mentioned by other speakers in which such blebs had given rise to the condition.

It was stated that at the Brompton Hospital at least ninety per cent. of the cases of pneumothorax were due to tuberculous disease, and a large majority of the remaining ten to rupture of emphysematous blebs. It was also suggested that some cases occurring in the course of fever might be caused by the rupture of scattered pyæmic abscesses, which are known sometimes to complicate bad cases of fever.

The report of the Army Medical Department was issued last week. It is a heavy and important record of the medical statistics of the army, but a good deal of the interest attaching to it is lost when it is observed that the report is for the year 1894. Surely the staff is in a position to bring out its report somewhat sooner. Why should it be a year behind most other heavy reports? In the United Kingdom the returns compare favorably with those of the previous year. In Egypt and the colonies there was decided improvement. In India there was increased sickness.

The report for the same year of the Registrar-General has also appeared and is notable as recording the highest standard of public health attained since the records commenced. The death rate was only 16.6 per thousand of the population. This is the lowest we have reached. The zymotic rate was low except in the case of diphtheria. The deaths from phthisis were also fewer. But cancer shows a larger number of deaths than previously reported, and it looks as if this dire disease is increasing, or perhaps it may only be that cases are now recognized as cancerous which were formerly diagnosed otherwise.

"Shadow-photography," "Roentgen's rays," "dark-light," "X rays," "Crookes' tubes," "cryptoscope"—such are the terms garnishing our daily conversation, which is further interspersed with cases of successfully fixing the position of foreign bodies and speculations as to the possible uses to which the new discoveries may lead. Interesting experiments have already been made as to the effect of the rays on microbes. The question arises whether the phenomena may not be as much electrical as optical. Optimistic opinions of new remedial power are here and there heard, while the more general view inclines to caution, expecting curious scientific developments and a readjustment of theories rather than immediate therapeutic results. No doubt your physicists were equally at work and your physicians keeping also an open mind.

Dr. Armand Ruffer has been appointed professor of bacteriology at Cairo and has accordingly resigned the directorship of the British Institute of Preventive Medicine.

There were no deaths from small-pox in London last week and the number under treatment on the ships fell to fifty-four. The outbreaks at Cardiff and Gloucester are giving cause for anxiety in those towns.

Another of our distinguished retired army surgeons

has died, viz., Surgeon-General J. Ekin, C.B., on the 14th inst., aged sixty-seven. He had seen much field service and had been principal medical officer at Nutley.

The discussion on the parasite of malaria was commenced before the Medico-Chirurgical Society on the 11th inst. with a paper by Drs. Robert J. Marshall and George Thin having special reference to the malarial fevers of the south of Spain. Before giving an account of their own investigations these gentlemen reviewed the results of the Italian authorities and exhibited a number of diagrams and lantern slides. It will hardly be necessary to give an abstract of the results of the Italian workers, as they are already known on both sides of the Atlantic. But one or two points of interest may be mentioned. The period of incubation, for instance, has been determined by Bignami and Bastianelli to be from eleven to fifteen days for a quartan fever, six to twelve days for tertian, and two to five days for the summer-autumn fevers of Rome. The short incubation of these last is an indirect proof of the short cycle of the quotidian parasite. The variation in the time seems to depend on the variety of the parasite as well as to some extent on the amount of blood injected in these experiments. The interval after the administration of quinine before the animals experienced a relapse was assumed to depend on the number of living spores left by the quinine, for it appears that the drug rapidly kills any spores set free by segmentation but cannot reach those which are protected by the substance of the red corpuscles. But Baccelli injected a gram of quinine into a vein a few hours before a paroxysm was expected. It was not prevented, although the spores which were free were killed. When the drug is administered it is found in the blood in the largest quantity during the first six hours. To insure the destruction of a generation of the parasites Golgi found it necessary to inject as much as a gram into the blood, which is equivalent to one in five thousand; but even after this amount the crescentic form of parasite has been found, though perhaps this might disappear after a long course of the remedy. The parasites were not killed by the administration of arsenic.

The observations of the authors of the introductory paper relate to the parasites of malarial fevers in the Province of Huelva. They found that the parasites included those observed in quartan and tertian fevers, described by Golgi, whose observations they verified in every detail. Cases were also met with in which the quotidian parasite was observed, and these cases they classed as irregular fevers. In some the crescentic form was not seen; in others they found a parasite resembling that seen in the early stages of quotidian fevers, but in later stages this was associated with the crescentic form. Whether this is a separate species seems yet undecided, though the drawings shown seem to indicate an unbroken series from the young spore to the fully developed crescent. The question was discussed as to how the parasite gets admission to the body, and the facts gathered at Huelva were held to prove that it was not carried by currents of air, but, as in other places, that combined heat and moisture favored access to the human body, especially when these conditions were accompanied by disturbance of the soil. Further, the facts supported the conclusions of the Italian authorities that the poison is not conveyed by drinking-water nor yet by mosquitoes and other insects playing the part of intermediate hosts. The reports of these cases were furnished by Dr. Marshall, who had attended the patients and examined the freshly drawn blood, while the dry and stained preparations were studied jointly by both Dr. Marshall and Dr. Thin.

Dr. Curnow congratulated the authors on the care they had taken in obtaining these results and went on to say that it was a curious circumstance that, while in England we are discussing whether a given variety of plasmodium produces a fixed variety of fever, Surgeon Lieutenant-Colonel Lawrie declares that a plasmodium has no connection with fever and that the pigmented bodies described are only the vagaries of a leucocyte. But if that is the result of his Indian work, it does not accord with Dr. Curnow's, who said he had been well acquainted with the plasmodium since Professor Cruikshank showed him some brought from Rome eight or nine years ago. He had often seen it since at the Seamen's Hospital. Two distinct questions were raised by the paper. 1, The varieties of plasmodium and their relation to fever; and 2, The question of the etiology and spread of the fever. As to the first question, the circular or amebic form was common to all varieties of malarial fever. The pigmented forms displayed so many differences that they could not be made foundations of varieties of fever. He recognized four forms of plasmodium: 1, The circular found in all acute cases and which might at a certain period become, 2, the flagellated form of which he had seen many examples, chiefly in quotidian and tertian but also in quartan fevers; 3, rosette forms found only in tertian and quartans; 4, crescentic forms met in all fevers, especially chronic cases and those least acted on by quinine and therefore very intractable. Possibly the crescentic forms were derived from the circular or ameboid, and he asked if we had any evidence that a distinct fever was associated with a crescentic plasmodium. He did not consider that the suggestion of the author, that there might be as many varieties of parasite as of fever, was supported by the cases they related. In one of these quinine had been given, which interfered with the result, and another was diagnosed solely from microscopic appearance. He considered it necessary to study each variety in cases unaffected by quinine, and to start with the microscopic appearances was of little use. As to whether the parasite was air-born or water-born we could not judge from the experience of local areas, that the opinion that it was air-born was universally accepted, but it could not be said that infection might not take place from drinking-water. Bourdin found that in one hundred and twenty soldiers returned by ship from Algiers to Marseilles one hundred and three of them, who drank marsh water, suffered from malaria, but the sailors who had other water remained well. Other observations were mentioned to the same effect. As to the mosquito hypothesis, finding the flagellum in the mosquito was a long way from finding the plasmodium in man. As to treatment, he urged the importance of prevention and advised those going into a malarial district to take quinine every morning with their coffee. He referred to the experience of officers spending five months in laying cables on the west coast of Africa, calling frequently at the ports but continuing on this plan almost free from malaria. The debate was then adjourned.

Use of Curette.—The dull curette is a useful instrument in scraping out retained secundines after abortions, or portions of intra-uterine or adenomatous growths for macroscopical and microscopical examinations. The sharp curette is a much safer and more efficient instrument for this purpose. . . . In endometritis the hypertrophic membrane should be removed with the sharp curette; blunt curettes are useless for this work. If a surgeon must use such, because of the supposed danger attaching to the sharper instrument, it is questionable whether he should do the operation at all.—*American Text-Book of Gynecology.*

SHORT-SIGHTED MEDICAL DIRECTORS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read with much interest your editorial upon family history, etc., as connected with life-insurance examinations.

I have had a very large experience as an examiner and thoroughly agree with your remarks that "great injustice is done in very many cases" by the medical director.

I believe that one of the crying injustices is due to the fact that all rejections are made known to a central bureau and by this bureau are made known to every company in the United States, and undue allowance is made therefor.

Your remark that "we are convinced that the applicant for insurance is not given half a chance" is too true.

Take the case of an applicant known to me, who was rejected for sugar in the urine by an incompetent examiner for a prominent company. The bureau was notified and through it all other companies. The applicant was also notified.

Feeling certain that he was sound, he went to his family physician, an unusually competent man, who found no sugar after repeated tests. The applicant, knowing nothing of the bureau, made repeated applications to many companies, in every instance upon a recommendation of the local examiner, and was turned down by every one.

His family physician was appealed to and he wrote a medical director the facts. The director compelled the applicant to have his urine examined at his own expense every two weeks for three months before he would accept a favorable report from his own examiner.

This means that the favorable report of a half-dozen examiners was not able to overcome the unfavorable report of an unknown examiner for another company.

This is a rank injustice. The bureau is a valuable institution, but directors should use it, not abuse it.

When an applicant protests that he is a sound man in spite of a rejection and furnishes evidence of it, the company should name a board of three examiners, who should make a test examination which should be final. If they accept him, the bureau should be notified and the name erased from the insurance black list.

R. M. STONE, M.D.

OMAHA, NEB., February 25, 1896.

FAMILY HISTORY AND TUBERCULOSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your remarks called out by the statistics of Dr. Marsh of the Mutual Life Insurance Company in regard to family history and phthisis, will, I am sure, be widely appreciated by medical examiners for insurance companies. The injustice which you point out as often inflicted upon individuals from a blind following of rules founded on such statistics is matter of common observation.

But it occurs to me to mention in this connection the disproportionate value placed upon "family history" by these companies, as against the generally accepted theory of the etiology of phthisis at the present day. Heredity has steadily declined in importance with all authorities, I think, as an etiological factor, while the infectious and contagious character of the disease has grown. This fact is theoretically recognized by some companies, the Equitable at least, but I have yet to learn that any yet conform in their questions or decisions as to acceptance of risks to the latest knowledge of the disease.

Your quotation from Fagge, that it is "impossible to draw a line between hereditary and accidental tuberculosis," makes the determining of the exact cause of

an individual case in a family imperative. If there is only an "accidental" case in a family it should not of course prejudice the case of the applicant. We all know that constant association with a phthisical subject, either in the home or in the store, shop, or mill, as husband or wife, or as fellow-workman, is more to be feared than a phthisical father, mother, uncle, aunt, brother, or sister not in such association. It would seem to the casual observer or inquiring examiner that a question founded on such facts as these would be quite as consistent with recent views of this disease as those regarding family history, immediate and remote.

C. S. CAVERLY, M.D.

RUTLAND, VT., February 25, 1896.

PERSONAL CONDITION IN ESTIMATING A LIABILITY TO CONSUMPTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of February 22d you have a long editorial notice of my report on the "Value of Family History and Personal Condition in Estimating a Liability to Consumption." Your criticism of the work is decidedly unfavorable, but you have so misinterpreted it that you attribute to me opinions which I do not hold and conclusions which I have not formulated. You say that "the conclusions are false, misleading, and unscientific. . . . We hate to think of the gross injustice which will be done and the suffering inflicted on widows and orphans where the bread-winner has been 'turned down' because of a partial or strict adherence to such utterly false conclusions."

I do not care to enter into a discussion or refutation of your criticism, but, as my report has had a limited circulation and your notice has been read by thousands of our examiners, I would ask, as a matter of justice, that the "conclusions" be given in the exact words of the report. I am entirely willing to leave the decision as to the justice of your criticism to the readers of the MEDICAL RECORD.

The summary of my report was as follows:

"The statistics given in this report warrant the following conclusions:

"1. That the history of consumption in any member of the immediate family increases the probability of its appearance in an applicant.

"2. That consumption in a brother or sister is at least of equal importance as when it has occurred in a parent.

"3. That persons who are under the standard or average of weight are much more liable to consumption than those above this standard. That the peculiarity of constitution which is indicated by the inability to take and assimilate a proper amount of nutriment indicates a susceptibility to phthisis, or at least is a reasonable suspicion of such predisposition.

"4. That persons who exhibit a robust and well-developed body have little susceptibility to consumption.

"5. That the personal condition of weight and robustness has far more value than the family history in diminishing the liability to consumption; therefore

"6. The evidence presented by a well-developed body may outweigh the suspicion attached to unfavorable family record.

"7. That these influences of family history and personal weight are of the same grade for every age, and their importance is not lessened by the fact that the individual has reached middle life.

"In deciding upon the eligibility of an applicant for life insurance, in whose case there is a suspicion of future danger from consumption, his personal condition is of the first and his family record of the second importance. Whenever he presents a robust physical appearance, with a weight at least equal to the standard or average as given in our tables, he may be ac-

cepted, notwithstanding any taint in the record of his family. In our experience such persons have a small liability to consumption, although not protected from it. If, however, his weight does not come up to the average and he gives a history of consumption in brothers, sisters, or parents, he is to be regarded as an unfavorable risk. This does not mean that all such persons are to be absolutely excluded from insurance, but each case must be carefully scrutinized, and the decision based upon the circumstances of occupation, character, past history, etc. When these are favorable, insurance should be given on terms most advantageous to the company, by limiting the amount or modifying the form of policy; when unfavorable, the applicant should be either postponed until he has gained sufficient weight, or else be absolutely rejected."

E. J. MARSH, M.D.,

Medical Director, The Mutual Life Insurance Co. of New York.

NEW YORK, March 4, 1896.

THE INSANITY LAW AND THE LUNACY COMMISSION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial comments on the proposed "Insanity Law" are of great importance and ought to be brought to the attention of the legislature. It is apparent that the commission should be enlarged to meet existing conditions. The present commission has, in one of its reports, stated that the patronage of the institutions for the insane in this State exceeds that of the canals and prisons. It seems incredible that our legislature can now intrust to three men, not one of whom is known as a successful business man, such enormous powers over patronage and in the expenditure of \$4,000,000 of public money.

Your plan of enlarging the commission is excellent, for it brings into that body a special representative of the people of each hospital district. And it seems to me particularly important that New York and Kings counties should have each a member, as they would represent institutions having in care half of the insane in the State. Another good point in your plan is the proposition that the commissioners should serve without pay, as do the commissioners of other State boards which have equally responsible and onerous duties to perform. Thus the State would save the thirty to fifty thousand dollars which the present commission receives.

MANHATTAN.

NEW YORK, March 7, 1896.

ACETYLENE NOT EXPLOSIVE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The letter from Dr. Legge (MEDICAL RECORD, February 22d) seems to me to involve a serious misapprehension of what constitutes an explosive gas. The explosion of acetylene is governed by the same principle as that of other hydrocarbon gases, namely, the gas requires to be mixed with a certain amount of oxygen in order to form a combustible mixture. The explosion which is reported in Dr. Legge's letter is not of acetylene, which by itself is no more explosive than so much chalk. But the accident was dependent on a mixture of the acetylene with air, and precisely similar accidents are constantly happening with common illuminating gas. True explosive gases are known to the chemist, that is, substances that will of themselves decompose with more or less violence when heated, but acetylene has no such property. It is obviously a mistake to apply the term explosive to a substance which requires a specific admixture of air in considerable proportion to produce the property of rapid combustion.

HENRY LEFFMANN.

715 WALNUT STREET, PHILADELPHIA.

Therapeutic Hints.

Leucorrhœa of Pregnancy.—A five-per-cent. solution of lactic acid.—DORLAND.

Antitoxin Treatment.—The eminent pathologist, Virchow, who at first criticised the antitoxin treatment, presented some statistics at the Berlin Medical Society where the death-rate had been reduced from forty-seven to thirteen per cent. "All theoretical considerations," he said, "must give way to the brute force of these figures," and he held it to be the duty of every doctor to use the serum.

Mentholated Oil for Purulent Rhinitis.—Fogerau cured a case of acute primary purulent rhinitis due to staphylococcus albus and staphylococcus aureus by spraying ten-per-cent. mentholated oil into the nares and pharynx five or six times daily.—*Ann. d. Malad. de l'Or., du Lar., du Nez et du Pharynx*, 1895, No. 12.

Adenoid Vegetations of the Naso-Pharynx.—Arslau, of Padua, concluded after extended clinical study that adenoid vegetations of the naso-pharynx occur frequently in Italy. The primary causes are heredity and dyscrasic diseases, the secondary causes humidity and infectious processes. He employs the Moritz Schmidt incision, followed by scraping with the finger. As an anæsthetic he finds ethyl bromide preferable. In all cases where adenoid vegetation is detected it should be removed and all children should be subjected to a naso-pharyngeal examination before being admitted to public or private schools or other institutions.—*Ann. d. Malad. de l'Oreille, du Larynx*, etc., 1895, No. 10.

For the Abdominal Pains of Muco-Membranous Enteritis.—

R Menthol	gr. iij.
Alcohol	sufficient to dissolve.
Simple syrup	fl. ʒ vi.
Water	fl. ʒ iij.

M.

—MATHIEU, *Revue de Thérap.*

Rhinoscleroma.—Dr. W. Freudenthal says rhinoscleroma is a chronic hypertrophic inflammation of the mucous and submucous tissues of the upper respiratory organs, commencing with the nose and extending down to the trachea. The disease usually begins with thickening and induration of the skin on the septum cutaneum narium. The nose becomes broadened and flattened and its tip approaches the upper lip.

Choroiditis.—In the treatment of rheumatic and gouty choroiditis plastica and serosa pilocarpine should be administered every other day for the purpose of inducing profuse sweating. Two one-fourth grain doses at an interval of an hour will be sufficient. After taking the first dose, which is made more effective if given in a large glass of hot lemonade, the patient should go to bed in a warm room. The sweating will last from two to three hours. The patient should remain in the room the remainder of the day, so that there may be no vasomotor disturbances caused by atmospheric exposure.—*Tri-State Med. Journal*.

Dr. F. W. Ross calls attention to the fact that there is a pouch behind the liver and another behind the spleen, and that he often finds it necessary, after having removed a large quantity of ascitic fluid, to pass a sponge above a ridge formed by the peritoneum as it joins the transverse colon to get the fluid that lodges in these pouches. The fluid finds its readiest exit backward and outward toward the right side. He recommends a drainage tube passed in this direction as

a safeguard against the extravasation of bile from an unclosed common duct.—*Canadian Practitioner*, January, 1896.

Brandt Treatment of Typhoid Fever.—Dr. Nogier (*Lyon Méd.*, lxxx., 1895, p. 409) writes as follows: "Concerning the treatment of typhoid fever, the statistics of the fourteenth corps show that a smaller percentage of mortality has been obtained by those surgeons who used the cold-bath treatment and employed it systematically till there was a permanent fall in temperature. Not to give patients the benefit of this chance is to incur a responsibility to which no surgeon should expose himself, and from which he cannot excuse himself by arguing that he has not the proper means to carry out this line of treatment. It belongs, in fact, to all those having hospital service in charge to organize in such a way as to make this treatment easy, and, if there be need, to make urgent demand at the proper time for the material and the personnel required."

Burns of Eyelids.—Drs. Landolt and Gygau (*Précis de Thérapeutique Ophthalmologique*) recommend:

R Cocaine hydrochlorate gr. xlv.
Lanolin gr. lxxv.
Vaseline,
Distilled water āā gr. ccc.

This preparation may be used for slight burns, or Carron oil or finely pulverized bismuth may be used.

For burns of the second degree one of the following may be employed:

R Cocaine hydrochlorate gr. xxij.
Salol gr. xlv.
Vaseline gr. cccxxv.
R Iodoform gr. lx.
Extract of conium gr. xxx.
Carbolic acid gr. 3/4
Rose ointment gr. ccccl.

Before the application of the ointment the blisters should be opened and carefully washed.—*N. Y. Med. Journal*.

Colica Intestina.—

R Bismuthi subnit. 15.
Pulv. cinnamomi 4.
Sacch. alb. 60.
Half a teaspoonful each day before dinner.

—H. ROSATINSKY.

Antistreptococcic Serum was injected (six cubic centimetres) in an infant of three weeks presenting an umbilical erysipelas reaching to the hypogastrium.

The following day there was general improvement and a second injection was given, followed in three days by a third. There was some extension of the process and sphacelus of the scrotum occurred, but the infant recovered.—*STEELE, Brit. Med. Journal*, December 7, 1895.

Gonorrhœa.—

Glycerin,
Ol. vaselini āā ʒ i.
M. Sig. Apply locally with a sponge at night.

—BARTHOLOW.

Frost Bite, or erythema pernio, recurring as it so habitually does with the advent of cold weather year after year, merits attentive consideration.

Treatment must vary with the lesion present.

When the skin is red, tense, and shiny without ulceration moist dressings should be applied. Compresses wet in a decoction of walnut leaves (ten to fifteen grams of leaves to a litre of water) should be applied and covered with an impermeable tissue. After the irritation is calmed apply:

R Boric Acid 1 gm.
Tannin 0.30 cgm.
Vaseline 10 gm.

Or apply:

R Starch,
Lycopodium āā 10 gm.
Tannin 0.30 cgm.

In slighter forms lotions with the decoction morning and night will suffice, and after the above applications gloves should be worn during the day.

In ulcerated lesions wash with Van Swieten solution (90 centigrams of corrosive sublimate, 96 grams of alcohol, and 928 grams of distilled water) and apply compresses with the same diluted with an equal quantity of water. If this does not succeed apply Vidal's red plaster (minium, 2.50; cinnabar, 1.50; diachylon, 26) or zinc-oxide plaster.

General treatment must not be neglected, especially in scrofulous subjects and those of delicate complexion.

Prophylaxis: Order exercise, the avoidance of exposure to prolonged cold, and the sudden passage from cold to heat, and *vice versa*. Brocq has found successful the following, which may be taken at intervals throughout the winter, acting as a vasomotor regulator of the circulation:

R Quinin. sulph.,
Ergotine āā 0.05 cgm.
Pulv. digitalis fol 0.005 mgm.
Ext. bellad. 0.001 mgm.
For one pill. Two to four to be taken daily before eating.

Stated Meeting, March 5, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Pneumonia as a Complication of Diphtheria in Children.—DR. HENRY W. BERG read the paper. (See p. 365.)

Pneumonia Always an Infective Process.—DR. HERMAN M. BIGGS thought it was pretty generally accepted now that pneumonia was always an infective process. With the exception of lobar pneumonia—which perhaps might be due to a specific micro-organism, the pneumococcus of Fraenkel, although we were not sure of even that—the other forms of pneumonia and broncho-pneumonia were not due to a specific infection, but might be due to a number of different micro-organisms. They might be due primarily to the Loeffler bacillus, but almost invariably when this bacillus was present there were also others, as streptococci and even staphylococci. None of these, he believed, would produce pneumonia unless there were other conditions reducing the vital resistance. In this respect these pneumonias differed from scarlet fever and measles, to produce which only exposure to infection was required. With this explanation, he could easily understand why broncho-pneumonia so frequently followed diphtheria. There were the depressing influence of diphtheria and the favorable conditions for the entrance of the infectious germs into the bronchi. In hospitals, owing to overcrowding, etc., the conditions were more favorable for the development of complicating broncho-pneumonia than in private dwellings. Isolation of cases of broncho-pneumonia complicating diphtheria from those of diphtheria not so complicated was desirable, yet he did not think it was absolutely necessary. In some other hospitals besides the Willard Parker the development of one case of pneumonia after another seemed to have left little doubt of infection, for after the wards had been thoroughly aired a number of days and disinfected the septic pneumonias ceased to occur. On speaking of this to Dr. Janeway, the latter recalled a period when about fifty per cent. of the cases of small-pox in the Riverside Hospital developed erysipelas. The wards were then emptied and renovated in a radical way, and thereafter no more cases developed erysipelas. As to the pneumococcus, case after case of pneumonia had been known to develop in the wards of certain hospitals, showing beyond question infection of the ward from this germ. In broncho-pneumonia complicating diphtheria he thought the chances of infecting other patients would be largely diminished if we could isolate such cases from others of diphtheria in the same hospital, but the difficulties in the way were considerable.

The next point was to get the best possible ventilation and the largest possible floor space, to regulate the temperature, and to keep the patients under the best possible sanitary conditions. He agreed with all Dr. Berg had said regarding treatment. He was glad that he had condemned antiseptic inhalations. They were a source of a great deal of harm, for they did not reach the seat of the disease and disinfect the local process, while they kept the air of the room surcharged with moisture and usually at a high temperature. It was a question of resistance of the vital organism to the germs, and anything which tended to depress the vital resistance exerted by so much a deleterious influence. If a well person should stay in a room twenty-four hours where there was a boiling kettle saturating the

air with carbolic acid, compound tincture of benzoin, or some such substances as were so commonly used, he would begin to realize how enormously debilitating it was.

Oxygen was useful. Cold was the only agent which should be used for pyrexia. He knew of no contra-indication to its use except collapse. He preferred mild cold, as by sponging with alcohol and water, and if this was not sufficient the pack or bath could be employed. Poultices were an abomination. They should never be used in pneumonia unless to relieve the pain of dry pleurisy in adults.

Regarding a streptococcus antitoxin, if a successful one could be secured it would, of course, be the ideal agent for treating those cases of infection due to the streptococcus, but it must be remembered that in a very considerable proportion of cases other organisms, such as the pneumococcus of Fraenkel, took part.

DR. WILLIAM H. PARK mentioned the last two cases with autopsy and bacteriological examination at the Willard Parker in their bearing on the questions under discussion. In one the patient was benefited under antitoxin treatment but after some days developed the temperature of pneumonia, and at autopsy they found in the lungs streptococci and other germs of mixed infection. In the other case it was clear that the child had pneumonia from the first and might have died even without laryngeal diphtheria, for which it was intubated.

Regarding isolation, while it would be on the safe side, yet he was not convinced that about equally good results would not follow increase of air space without isolation. He doubted whether the streptococci and other germs of mixed infection were present in the air; at any rate, he never found any streptococci in the dust of the wards. The greater number of cases of broncho-pneumonia complicating diphtheria in the hospital as compared with private dwellings was probably due to the depressing influence of having so many sick people together and to the lack of air space. Regarding the influence of treatment on the germs, we could only expect diphtheritic antitoxin to influence the Loeffler bacillus or its toxins. Laryngeal diphtheria was more likely to be complicated by pneumonia than diphtheria situated higher.

The last two years prior to January they had kept the temperature of the wards as high as 80° F., theorizing from the fact that diphtheria was less prevalent in summer than in winter. Doubtless the theory was wrong; it was impossible to have proper ventilation with the temperature at 80° F. and the past five weeks they had reduced it to 70° F., and during this time there had been less pneumonia and more of the cases recovered which did have pneumonia.

One of the visiting physicians, Dr. Winters, had claimed that the larger number of cases of broncho-pneumonia occurring during the use of antitoxin could be attributed only to the hypodermic injection of large doses of serum albumin. Now, no germs were injected with the serum, and as pneumonia was an infective disease, the only way in which the serum could favor its development would be by undermining the system until it could no longer resist the streptococci entering through the air passages. The real explanation of the apparent increase of pneumonia complicating diphtheria since the introduction of the antitoxin treatment was found in the fact that prior to that period the patients did not live long enough to have death attributed to that cause. The very fact that the antitoxin counteracted the diphtheritic poison and placed the patient in the way of recovery gave the mixed germs more time in which to produce pneumonia. But that was a credit to the antitoxin treatment, and statistics of the hospital during its use showed fifty per cent. of recoveries as against twenty per cent. before.

DR. JOHN W. BRANNAN had come to the conclusion, after considering the apparent increase of cases of broncho-pneumonia at the Willard Parker during the past year, that it was due to the fact that antitoxin had saved a larger number from diphtheria, and these could go on to develop pneumonia should infection occur.

As to causes of complicating pneumonia, Dr. Brannan had found, in the first place, that only about half the floor space was allowed each patient that was allowed in other similar hospitals. Lately they had increased it, but they had not been able to give more than eighty to eighty-five square feet. Another marked improvement had been the lowering of the temperature of the wards. Formerly the air felt hot and stuffy. A third measure which he regarded as of some importance had come to him on reading an article in the *MEDICAL RECORD* by Dr. Seymour, of Troy, on drainage away from the lungs by gravity in operations on the tongue, etc. At the hospital they now raised the foot of the bed ten inches, with a view to cause drainage away from the larynx and prevent infection of the lower air passages.

Urges no Treatment except Bathing.—Dr. Brannan felt like urging no treatment except bathing the patients, and he found that the temperature could usually be controlled by a tepid bath of about 90° F. If one chose, the child could be kept for a longer time in a sheet wrung out of warm water after the bath. It acted beneficially also in increasing the depth of the respirations.

DR. W. P. NORTHRUP said, concerning the inspiration of fluids, etc., the schnupf-phenomenon, that Dr. O'Dwyer and he had mixed a little lampblack and materials of other colors with the milk given intubated infants, but they had never found any of it below the distal end of the tube in cases which came to autopsy. The same fact had been observed by the Germans.

Broncho-Pneumonia or Lobar Pneumonia?—Dr. Northrup said that in children under two years of age pneumonia was anatomically broncho-pneumonia, even when its distribution was lobar. The reason was that in the fetus up to the sixth month there were bronchia but no alveoli; for a few weeks after birth the bronchia continued to occupy much of the pulmonary space, and there was a large amount of loose connective tissue around the bronchia. In the adult this became thin and was less subject to infiltration, and we saw lobar pneumonia. The adult form of pneumonia might be seen after the second year, but not often until the fifth year.

The severity of infectious diseases seemed to be increased by numbers, striking examples of which he had seen in epidemics of measles. The difference in his results from intubation could hardly be accounted for in any other way than by the different surroundings under which it had been performed, being better in weather when windows could be kept open, worse in winter when ventilation was poor.

As for treatment, he swabbed the mouth and used the spray in this and other infectious diseases. Anything which was too hot he cooled down with water. If water was not cold enough he used ice. He wished also to say a good word for the poultice. It was our hobby to go to extremes, and he thought it was going to the extreme to entirely condemn poultices. He was, however, opposed to their continuous use.

DR. WILLIAM WATKINS SEYMOUR, of Troy, told how he had come to employ the gravity position in operations on the larynx, trachea, and tongue. Out of his last ten intubations there had been eight recoveries, and in only three of them had antitoxin been used. He believed the much-abused poultice had been used in all. The fatal cases were in patients whose parents did not faithfully carry out instructions. Young

children could be kept several days with the feet elevated without much inconvenience.

Sustain the Right Heart.—DR. ANDREW H. SMITH said that in pneumonia the right ventricle was constantly called upon to do enforced duty in driving the circulation through the obstructed lung. Moisture and confined air interfered with respiration and impaired the blood. In no other disease had he seen so much benefit from the inhalation of oxygen as in the broncho-pneumonia of children, but ordinarily its use was not begun early enough. Another indication was to divert the blood from the veins to the arteries. Employ arterial dilators. Digitalis was responsible for loss of life in many cases of obstructive disease of the lungs, for it contracted the arterioles.

Carbonic Acid per Rectum.—DR. ACHILLES ROSE suggested inflation of the rectum with carbonic-acid gas, from whence it would be carried by the venous circulation to the lungs, where in the alveoli an exchange with oxygen would take place, yet there would be no more oxygen absorbed than was in proportion to the carbonic-acid gas. It had first been recommended in consumption by a Frenchman, but exaggerated hopes had led to its abandonment. Dr. Rose thought he had obtained benefit from it in whooping-cough.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 7, 1896:

	Cases.	Deaths.
Tuberculosis.....	106	108
Typhoid fever.....	6	3
Scarlet fever.....	115	8
Cerebro-spinal meningitis.....	0	0
Measles.....	441	24
Diphtheria.....	225	30
Small-pox.....	0	0

A Sign of Death by Exhaustion from Insufficient Nourishment in Young Children.—According to the Berlin correspondent of the *Medical Press*, Dr. Seydel asserts that in all cases in which death is brought about in young children by insufficient nourishment, total disappearance of the thymus gland is an invariable phenomenon. Whether this disappearance may not also be brought about by exhausting diseases, such as fevers, requires further observation. It is to be accepted as probable, as the thymus gland must be looked on as, to a certain extent, a reserve material, and it is highly probable that it is drawn upon to supply nutrient material that may be wanting. Where organic changes are absent and where on section of emaciated children there is absence of the thoracic glands, it may, according to the author's observations, be taken as a more certain sign of exhaustion by deficient and unsuitable nourishment than narrowing of the lumen of the intestine, which, in point of fact, is, as a rule, not present.

Feeding the Public with Disease Germs.—In a recent issue *The Sanitarian* speaks of the condition of the city of Brooklyn in the following manner: "The abominable practice of feeding the dust of disease germs of every kind to the people, which obtains throughout the city in default of well-appointed markets. The sidewalks of the streets are the places of display for marketable food of all kinds. Meats, vegetables, and fruits of all kinds are a part of the stock in trade by almost every grocer in the city and

many other storekeepers. From the time of the opening of their stores to the time of closing them, their food supplies are displayed on the sidewalks and dusted throughout the day with horse manure and every other kind of disease dust afloat in the air, from scabies to tubercle bacillus. At closing-time these supplies are piled into the stores without regard to cleanliness or order, as they are to be tumbled out again the first thing in the morning; and, needless to add, the stir within the stores is quite sufficient for the like dusting of everything served over the counters. The dark recesses, closets, stowholes, and cellars of such stores are thus loaded with disease-bearing dust, more or less putrescible according to the conditions of darkness, moisture and temperature, tainting everything that is served therefrom."

Respirability of Vitiated Air.—The breathing of air in which a candle flame will not burn is generally considered dangerous. In a paper by Mr. Frank Cloues, read before the British Association at the Ipswich meeting, the results of some interesting experiments were given. According to the *Popular Science Monthly* for March, 1896, it was found that the flames of ordinary candles and lamps were extinguished by mixtures which contained, on an average, about 16.5 per cent. of oxygen and 83.5 per cent. of the extinctive gases. A flame of coal gas, however, required for its extinction a mixture still poorer in oxygen and containing 11.3 per cent. of oxygen and 88.7 per cent. of the extinctive gases. These results have since been confirmed by a different method, which consisted in allowing a flame to burn in air inclosed over mercury until it was extinguished; the remaining extinctive atmosphere was then subjected to analysis, when its composition was found to be practically identical with that previously obtained from the artificial mixtures. An analysis of air expired from the lungs proved that it was also of the same composition as that which extinguished the flame of an ordinary candle or lamp. The average composition of expired air and of air which extinguishes a candle flame is as follows: Oxygen, 15.9; nitrogen, 80.4; carbon dioxide, 3.7. Now, an atmosphere of this composition is undoubtedly respirable. Physiologists state that air may be breathed until its oxygen is reduced to 10 per cent. The maximum amount of carbon dioxide which may be present is open to question, but it is undoubtedly considerably higher than 3 per cent. Dr. Haldane maintains that the above atmosphere is not only respirable, but would be breathed by a healthy person without inconvenience of any kind; he further states that no permanent injury would result from breathing such an atmosphere for some time. The conclusion to be drawn from these facts is that an atmosphere must not be considered dangerous and irrespirable because the flame of an ordinary candle or oil lamp is extinguished by it. The popular notion about such an atmosphere might often deter one from doing duty of a humane or necessary character.

Positions During Sleep.—In conversation with a *Sun* representative a physician of this city said that the phenomena of posture in sleep really offer a fruitful field of study. There is an important physiological meaning or significance in the different sleeping positions. The natural attitude adopted by young children when free to do as they please with their bodies and limbs is interesting. Puppies and kittens lie curled up during sleep just as they did before they were born. Now what is the natural position of babies during sleep? In nine cases out of ten, young children, when old enough to control their limbs and unfettered by clothing or cover, draw up their legs and bend their heads over in their arms. They simply

resume the position they occupied in embryonic life. Of course the trouble is in too many cases that our children are not allowed to sleep according to their natural inclinations and mothers and nurses interfere with the position most convenient for them. So, too, Indian babies are seldom allowed to sleep in the position they like best. The squaw bundles the little one into a motionless thing and often straps the child tightly to a board. But if you observe how babies sleep in warm climates, where they are not bothered with much clothing, you will find them sleeping in the natural position. Whether they sleep on mats of grass, on the warm earth, or in hammocks, the children lie in the curled-up position. My attention was first called to this position by the negro babies down South. There I often saw the negro mammy lay the black baby down to sleep on its stomach and wondered whether or not the child was comfortable. Since then I have found this practice common among mothers and nurses in southern countries. They know that their young ones like to sleep in the same position as do many animals—that is, with the stomach downward and the legs and the arms usually bent under them. After a while boys and girls of four or five years of age slightly change their attitude during sleep. They now lie on the side, face also on the side and with the legs drawn up, using one of the arms as a pillow. This is the position assumed by the higher orders of monkeys in their sleep. It is not until boys and girls grow up that they stretch out their limbs full length in sleep. The lower orders of monkeys sleep in the crouching position, with the head bent down upon the knee. There is one position during sleep that is peculiar to human beings. It is lying flat upon the back. No animal of its own choice takes such a position in sleep. One of the keepers at Central Park who has excellent opportunities for watching the animals there says that he has never found the apes sleeping upon their backs. We all know the usual disagreeable results of sleeping on the back. A person in sleep will often roll over flat, whereupon he or she sees strange sights and hears odd noises. Many a time I have seen mothers and nurses go to the child on its back, muttering or crying in sleep, and then gently turn the dreamer over on the side. The right side is preferred by many people, while some find the left side comfortable.

Cleaning Rusty Instruments.—Broder, in the *Journal of the British Dental Association*, gives a good method of cleaning rusty instruments. Put a saturated solution of chloride of tin in distilled water in a suitable vessel, immerse the rusty instruments, and allow them to remain over night. Rinse in running water and rub dry with chamois.

Mechanical Treatment of Pneumonia.—Dr. Reyold, of Bucharest, proposes a novel method of treating pneumonia—applicable only to the first stage—which is based on the axiom that two bodies cannot occupy the same space at the same time. He claims that the alveoli of the inflamed lung can be kept full of air by this method if resorted to in time, and that while full of air they of course cannot fill with anything else. All that is required for the application of this method, which is purely mechanical, is a spirometer of any kind that works easily and registers the amount of air it receives. The vital or extreme breathing capacity is the amount of air that can be expelled from the lungs after a full, deep inspiration. This is first ascertained on the basis established by Hutchinson, viz., that with every inch of stature between five and six feet the vital capacity increases eight cubic inches. Taking one hundred and seventy cubic inches as the standard for a male of five feet in height and eight cubic inches for every additional inch of stature, the

vital capacity is easily computed. Some deduction must be made for age and the female sex. Suppose the patient about to be treated is a male five feet seven inches in height: add fifty-six to one hundred and seventy, and we find his extreme breathing capacity in health to be two hundred and twenty-six cubic inches. The whole treatment hinges on maintaining his breathing capacity at or near this normal standard. All pleuritic pain which interferes with free respiratory movement must first be relieved, otherwise the preparatory deep inspiration which is essential would not be possible. The spirometer is now placed on a chair beside the bed, and the patient is directed to take a full inspiration and blow steadily through the tube until his supply of air is exhausted. After a few minutes' rest the operation is repeated, until the register indicates something near two hundred and twenty-six. The first effort may not give more than one-fourth of this amount but it will be gradually increased with each succeeding attempt, and half a dozen or more of such may be required to restore the normal breathing capacity. Thorough inflation of the lungs should thus be accomplished every hour in the beginning, and the interval can be increased as the number of respirations diminish to or near the standard of health. During the prolonged forcible expiration into the spirometer the pressure of the air in the lungs is markedly increased, and this pressure is exerted in all directions, downward as well as upward, resulting in the inflation of collapsed vesicles which had resisted the preceding full inspiration. Under these circumstances crepitant râles can be detected with expiration which are ordinarily heard only on inspiration. If all the pulmonary vesicles are thus filled with air at regular intervals it is evident, Dr. Reyodo claims, that they cannot fill with inflammatory products and that the second stage of pneumonia, or that of hepatization, cannot occur. By this method the functions of the diseased lung are retained, the interchange of gases continues, the capillary circulation is facilitated, and the right heart is not overtaxed. If cyanosis be present it rapidly disappears, and the feeling of oppression in the chest is relieved. If consolidation already exist nothing will be accomplished by this method, except to prevent extension of the disease and possibly to hasten resolution.

Why Negroes are Black.—Buffon, the elder, attributed the black skin of the negro to the influence of climate, heat causing the color. Orgeas agreed with Buffon. He had observed the feeble development of the pilo-sebaceous system among negroes, who are less hairy than the whites. Eijkmann enveloped vessels with human skin taken from Malays and whites, and found that the radiation of heat passing through a black skin was not more intense than that which passed through a white skin. In this, says the writer, he agrees with Melloni, Desains, Masson, and others, whose researches show that the color of an object or of a tissue has no influence on the obscure heat rays. On his carefully separating the fat from the skin, however, the natural conditions were changed. In the second place, the negro possesses a more developed vascular sudoriparous system than we do. He perspires more freely, and loses heat as an alcarraza does. There is evidently, says the writer, a close relationship between the influence of cutaneous pigmentation and the sudoriparous glands, and the two should be studied together. The skin of the negro becomes black after birth. Le Cat noted, in 1765, that the new-born negro was of a reddish color, the root of the nails and the scrotum alone being black. Two or three days after birth the skin began to turn black. Darwin also observed that the new-born Australian was of a brownish-yellow color. The Hindoo child

at its birth is white, although its parents may be perfectly black. The adult man's skin varies according to the race to which he belongs. Aside from heat, which has been especially spoken of, we must, says the writer, recognize other causes of equally great importance. Light seems to favor pigmentation of the skin. In uniform heat the light rays seem more active than the dark ones. The sun tans, and women use parasols and gloves to protect themselves from it; darkness, on the contrary, induces pallor. Aristocrats, who do not expose themselves to the air, have a light, transparent skin. The Japanese of distinction rarely expose themselves to the air without being veiled, and their skins are almost as white as those of Europeans. In Siam the high classes also have a light, transparent skin. The drawings of the ancient Egyptians, of the Etruscans, and of the Mexicans represent their women with light skins. A very brilliant light browns the skin even in cold countries. For instance, the Eskimos are brown. The luminous intensity of the long days is such that they are obliged to protect their eyes with glasses. In India the difference between the color of skins is more marked than among us, and Pariahs black as negroes may be seen side by side with Brahmans white as Europeans. The following type is very generally seen: Tall, straight, and slender; with long heads, a long face, and an aquiline nose. The Brahman is especially distinguished from the Pariah by his haughty bearing. The castes are very numerous, says the writer, and among them may be observed all the coffee-colored tints, the purity of which is not absolute. Among the Brahmans, occasionally, of two children in the same family one may be white and the other black. The same is seen among the Pariahs, although the white skin is more frequently observed among the former than among the latter. Certain castes which are held in slight estimation, such as the Moukhis and the Chamars, who live in the shade of the great palm trees, have an extremely white skin. Humidity favors pigmentation very distinctly. The countries where there are both great heat and great humidity contain the blackest people. The natives of Barbary are very much less deeply colored than the negroes of the Soudan, yet the uniform degree of heat there is 86° F., instead of 78.4° F., as it is on the coast of Guinea. The Egyptian has remained white notwithstanding a constant mixture with the black Nubians. The people who live in the dry section of the Nubian desert have a red skin; other races that are brown or that vary from a white to a chamois color also live in a dry country. The Abyssinians, however, in whose country the plateaux are well irrigated, are blacker. The blackest negroes in Africa are those who live in Guinea, where the greatest amount of rain falls. In Asia, says the writer, it is the same as in India. There is a close relation between the fall of rain and the color of the people. The more moist the climate is, the darker the skin of the natives. As one goes up the Ganges the climate becomes drier and the skin of the natives whiter. The Bengalese are black, but the Sikhs and the Radjpouts are of a dead-white color. In America it is the same. The Brazilians are generally darker than the inhabitants of the Andes. The Portuguese, who come from a rainy country, settled in Brazil, while the Spaniards inhabit the Andes and the dry La Plata section. Spain is very dry as compared with Portugal, and the Portuguese in Europe have the darkest skins of all Europeans. Heat, light, and humidity, says the writer, are, then, all causes of pigmentation. In dealing with these three causes alone and their relative influence, he says, the question of pigmentation of the skin is a very complicated one. For instance, persons inhabiting a mountainous district, where the climate is cooler, have a lighter skin

than those who live on the plains, although it has been seen that the Abyssinians are an exception to the rule. The native of Abyssinia is darker on the plateaux and lighter on the plains. In Peru the inhabitants on the coast have a lighter skin than those on the mountains. D'Orbigny observed that in America in the impenetrable forests the savages were lighter; the darkness evidently prevented pigmentation. What, asks the writer, causes the difference between the negro laborer exposed to the sun and the Brazilian savage who lives in the forest? The latter is more or less chocolate-colored, but not black. Are these facts, he asks, sufficient to prove absolutely Buffon's assertion that the color of the skin depends on the climate? Evidently not. If they were we should see the descendants of a white person become black and *vice versa*. The acclimated white man does not work in the sun, and he preserves his white skin as a Brahman does. Furthermore, it would require many generations to accomplish the change.—*New York Medical Journal*.

The Best Floor to Live on.—M. Korosi, the Hungarian hygienist, has lately investigated the effects of living in cellars and on ground and upper floors upon the duration of life. He found that the dwellers in cellars lived to about thirty-nine years and eleven months; those on the ground floor to forty-three years and three months; those on the first and second floors lived to forty-four years and two months; while those on the third and fourth floors lived only to forty-two years. All things being otherwise equal, the observations of M. Korosi may be accepted as showing the different effects upon longevity by the different selected planes of residence. The air of cellars or basements is never healthy, nor can such localities be ventilated except at considerable expense; the occupants are exposed to ground-moisture contaminations, to the impurities of body exhalations, and to foulness of the heavier ground air from the street and yard that of necessity pours down into such spaces. Those living on the first and second floors seem to enjoy the longest lease of life; this is as might be expected, from the greater freedom of the air of those floors from foul gases, microbes and germs, animal emanations, and from street dust. Much here depends, however, upon the character of the stairs; a steep, hard, stair tends to shorten the duration of life, while an easy, low-step stair, broken by easy landings at every eight or ten steps, will lengthen its duration. The spiral stairs, winding screw-like up in a narrow cylindrical space, are life shorteners. These stairs save space and destroy life, and are quite common in many parts of Europe, and where one has to climb them to the third floor the exertion is slowly but surely telling. The effects of stair climbing are visible in the two years of less life enjoyed by the inhabitants of the upper floors. These observations tally with those of Strassmann, of Berlin, with the exception that in Berlin the basements give less mortality than the immediate street floor, which speaks well for the humanity of the Berlin microbe. In Berlin the basements are occupied by a well-to-do class, whereas in Budapest, the point observed by M. Korosi, the basements are occupied by the very poorest. We should not neglect to observe that those who can afford a first or second floor flat are those who, as a rule, are better clothed, better fed, and capable of surrounding themselves with better hygienic conditions than the poorer of either the basements or of the upper floors. The dwellers of the first two floors are, besides, persons better off in the world and not so likely to suffer any physical ill effects due to occupation as their less fortunate fellow-mortals on the other floors, although we cannot overlook the fact that these better-favored ones

probably do more worrying and that they are apt to suffer more from diseases of the kidneys and of the circulatory system that arise from worry and anxiety; these favored ones would also be more likely to fall victims to acute brain or nervous affections than the others. So that were we to people the first and second floors with the less worrying and less perplexed but poorer class, the length of life of these would probably go far in excess of the forty-four years and two months.—*National Popular Review*.

Neurotic Inebriates.—Inebriety which arises from a defective nervous organization is very common in every circle of life. Many of these persons possess an unstable, invalid brain, with feeble and imperfect power of control, making it impossible to live along lines of consistent uniform thought and act. This often comes from inheritance and early disease and faults of nutrition and training. They become mental cripples, and need care and the control of others as positively as invalids from surgical disease. They are unfitted to care for themselves properly in society, or to adapt themselves rationally to surroundings, and early become wrecks, because they are without power for rational adjustment. They may be endowed with a highly organized brain, but so unstable and so easily disturbed that alcohol, opium, or other narcotics are most grateful drugs to cover up the real condition. The distress which follows strains and drains, and conditions of surroundings ill adapted to favor the normal conditions of living, finds relief in spirits. Quickly this brain infirmity becomes organized into progressive degeneration. This may continue for a long time without marked symptoms of active disease, but the deviations from health and nerve and cell degenerations continually increase. Friends, society, and even physicians fail to recognize this condition until extreme stages appear, and even then theories of free will, wilfulness, and capability of control prevail. These cases should have been recognized and protected from the first. Their lives and surroundings should have been ordered and regulated along fixed uniform lines. They needed protection from many conditions that were harmless to well persons. They needed direction and guidance where others could have walked alone. Many things in society and surroundings were injurious to them, and they should have been guarded against the danger which was inevitable. Such persons are without the mental stability to apply absolute rules on themselves, they cannot resist the contagion and infection of surroundings, they are helpless before the impulses of their organism, they need constant direction and support.

Many of these persons appear well, and only when they become marked inebriates is their real condition recognized. From this class are recruited the wild enthusiasts and neurotics, and the dangerous criminals and contagious degenerates who appear in mobs and advocate the most dangerous theories.

These cases of brain defects and disabilities must be recognized and proper remedies provided to protect individuals and society from the inevitable consequences of their unrestrained conduct.—*Quarterly Journal of Inebriety*.

Colliers and Cancer.—Mr. T. Law Webb, of Ironbridge, states that he has practised for twenty-five years in a district overlying the Shropshire coal field, and during that time he has been surgeon to two collieries, yet he has never seen a single case of cancerous disease in a collier who was working in the pits. "Moreover," he says, "an examination of the books of the district registrar shows that of all persons whose deaths are registered as due to malignant disease during the past thirty years, only two are described as 'coal miners.' Of these one I know positively had

long retired from the arduous occupation of coal-getting, and had for many years followed the more gentlemanly occupation of rat-catching. The other died in the workhouse, and had not worked in the pit for some time. It should be borne in mind that in this same locality cancer is very common and is often seen among the furnacemen, moulders, ironworkers, and general laborers." Another practitioner living in the same district is also unable to recall the case of any collier suffering from cancer. The immunity, however, does not extend to sarcoma. The explanation lies partly, Mr. Webb thinks, in the habitual cleanliness of the collier, who "tubs" daily as soon as he comes home from the pits, partly in the fact that his habits rarely lead him to drink water from casual sources. He goes to work early, and habitually in his working hours carries with him a quart can containing cold tea or coffee without milk. He always returns home to dinner, at which he usually drinks tea, or, if he can get it, small beer, while his supper consists of bread and cheese, with sometimes an onion and a pint of beer. The colliers in Shropshire are a temperate, peaceable, law-abiding class, not given to excesses of any kind. Though they are often seriously injured in their dangerous occupation, they survive the most extensive wounds and fractures, and although they look pale and anæmic they are in reality a healthy set of men. It would be extremely interesting if the surgeons who practise in the great coal fields of the North, and in the South Wales colliery district would give their experience upon this point of the alleged unequal distribution of cancer mortality in the population of coal-mining districts. If it is a fact that men working underground and not drinking much water are more exempt from cancer than those in a similar state of life working above ground and drinking from casual water supplies, we shall have a more tangible reason for suspecting cancer to be a water-borne disease than is afforded by any of the present theories or statistics.—*British Medical Journal*.

Big Words.—It is amusing and yet vexatious to see a worthy medical gentleman, whose ordinary conversation is in a simple and good style, suddenly swell up when he writes a medical article. He changes his whole dialect and fills his pages with a jangle of harsh technical terms, not one-third of which are necessary to express his meaning. He tries to be solemn and imposing. For instance, a physician recently devised a new instrument, and wrote it up for a medical journal under this title, "A New Apparatus for the Armamentarium of the Clinician," by which heading he doubtless hopes to make the fame of his invention "go thundering down the ages," as Guiteau said. Another writer wanted to say that cancer is an unnatural growth of epithelium. He took a big breath and spouted the following: "Carcinoma arises from any subepithelial proliferation by which epithelial cells are isolated and made to grow abnormally." Now, then, you know all about cancer. A writer on insanity illuminates the subject as follows: "The prodromic delirium is a quasi-paranoiac psychosis in a degenerate subject. A psychosis of exhaustion being practically a condition of syncope." The following is an effort to say that certain microbes produce the poison of erysipelas: "The streptococcus erysipelatosus proliferating in the interspaces of the connective tissue is the etiologic factor in the secretion of the erysipelatosus toxins." A large cancer of the liver was found at a post-mortem examination and reported about as follows: "A colossal carcinomatous degeneration of the hepatic mechanism." Still, the man of big swelling words is not always up in the clouds. If called to a case of accident, he examines the injury, and may inform the family in quite a simple and dignified manner that

their father was thrown sidewise from his carriage, breaking his leg and putting his ankle out of joint, but if he writes out the case for his medical journal, he gets up straightway on his stilts and says: "The patient was projected transversely from his vehicle, fracturing the tibia and fibula and luxating the tibio-tarsal articulation." Your man of solemn speech is peculiar. He does not keep a set of instruments—not he—he has an armamentarium. His catheters never have a hole or an eye in them, but always a fenestra. In gunshot injuries, a bullet never makes a hole in his patient, but only a perforation. He does not disinfect his armamentarium by boiling, but by submerging it in water elevated to the temperature of ebullition. He never distinguishes one disease from another, but always differentiates or diagnosticates it. His patient's mouth is an oral cavity. His jaw is a maxilla. His brain is a cerebrum, his hip-joint is a coxo-femoral articulation. If his eyelids are adherent, it is a case of ankylo-symblepharon. If he discovers wrinkles on the skin, they are corrugations or else rugosities. He never sees any bleeding, but only hemorrhage or sanguineous effusion. He does not examine a limb by touch or by handling—he palpates or manipulates it. If he finds it hopelessly diseased he does not cut it off—that is undignified. He gets out his armamentarium and amputates it.—*Address by Dr. Edmund Andrews, Chicago Medical College.*

Gastric or Duodenal Ulcer.—Dr. Osler, in his "Practice of Medicine," states that one of the causes of gastric or duodenal ulcer may be pressure, such as is exerted by shoemakers and others plying their usual vocations.

Asexualization of Criminals as a Prevention of Crime.—Dr. F. L. Sim, of Memphis, Tenn., argues ably in favor of sterilization of certain criminals in order to curtail the crime of rape.

Executions partake of revenge and are more than the demands of society require. It would be wiser to substitute a more humane and scientific punishment, and one that would at the same time convey a sufficient object lesson.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

HANDBOOK FOR THE BIO-CHEMICAL LABORATORY. By John A. Mandel. 12mo, 101 pages. John Wiley & Sons. New York. Price, \$1.50.

TEXT-BOOK OF GENERAL PATHOLOGY AND PATHOLOGICAL ANATOMY. By Richard Thoma. Translated by Alexander Bruce, M.D. Vol. I, 8vo, 624 pages, illustrated. Macmillan & Co. New York. Price, \$7.00.

DEAF-MUTISM. By James Kirr Lon, M.D., with chapter by W. H. Addison. 8vo, 369 pages. Macmillan & Co. New York. Price, \$2.75.

A TREATISE ON THE MEDICAL AND SURGICAL DISEASES OF INFANCY AND CHILDHOOD. By J. Lewis Smith, M.D. Eighth edition, revised and enlarged. 8vo, 987 pages, illustrated. Lea Brothers & Co. Philadelphia, Pa.

A TEXT-BOOK UPON THE PATHOGENIC BACTERIA. By Joseph McFarlane, M.D. 8vo, 359 pages, illustrated. W. B. Saunders. Philadelphia, Pa. Price, \$2.50, net.

THE TOXIC AMBLYOPIAS: THEIR SYMPTOMS, PATHOLOGY, AND TREATMENT. By George E. de Schweinitz, M.D. 8vo, 240 pages, 41 engravings, and nine full-page colored plates. Lea Brothers & Co. Philadelphia and New York. Price, \$4.00, net.

MIDDLETON-GOLDSMITH LECTURES¹—ON THE RELATIONSHIP BETWEEN INFLAMMATION AND SUNDRY FORMS OF FIBROSIS.

By J. GEORGE ADAMI, M.A., M.D. CAMB.,
PROFESSOR OF PATHOLOGY, M'GILL UNIVERSITY, MONTREAL.

Lecture I., Part II.

THE considerations I have brought forward up to this point should lead us to distinguish at least two main types of fibroid change associated with inflammation, one of which in default of a better name may be termed productive, the other replacement, fibrosis. In the former there is no causal relationship between the amount of new connective tissue resulting from the inflammatory action and the amount of tissue displaced; in the latter the amount of new fibrous tissue developed appears to be primarily governed by and proportioned to the extent of the destructive process, but both equally tend toward repair and arrest of injury.

This division will, I think, be found useful, and it will be seen that the leading forms of inflammatory fibroid change are to be grouped under one or other of these heads.

Under the first are to be included sundry localized fibroses of which the main forms are the focal areas of new connective-tissue growth induced by the presence of certain micro-organisms, that is to say, the more chronic or less acute forms of infective granulomata—the new growths (tubercles) induced by the tubercle bacilli, those (gummata) induced by the not surely determined organism of syphilis, the fibroid nodules caused by the presence of the leprosy bacilli, and, again, the more chronic type of actinomycotic and glanders lesions. Examples are not wanting of similar focal areas of fibroid growth induced by simple irritation. As such may, I think, be safely cited the earliest stage of one form of cheloid. Although, as I shall point out later, cheloid growths must be included among the fibromata, nevertheless, in many cases of what is sometimes termed and regarded as spontaneous cheloid, localized connective-tissue growths can be excited by local irritation of the surface. This was well observed in a case which has recently been very fully studied by one of my students, Mr. R. H. Martin. In this, the mere scratching with a pin was sufficient to give rise to the new growth. I am myself fully prepared to regard sundry cases of focal growth as non-inflammatory—as due to stimulation rather than to injury. The difficulty is that there is no line separating the one from the other; there is no sharply defined boundary between simple hyperplasia and that which is obviously reparative.

Merging at times imperceptibly into the previous group there are the capsular fibroses, comprising those cases of connective-tissue development induced around an irritant, whether infective or not. Here the zone or capsule of tissue formation is a develop-

ment of so much new material, laid down, it would seem, irrespective of previous tissue destruction in the immediate region of its appearance. Examples of this form will be immediately called to mind. Among the infective we have the thick capsules forming around obsolescent tuberculous masses, around chronic abscesses and phthisical cavities; among the simple irritative are to be classed the capsules developed around such foreign bodies as exercise little more than a mechanical irritation, whether those bodies be solitary and of large size, as, for example, impacted bullets, or minute and very numerous, as inhaled particles of coaly or silicious matter. Whether the capsules formed around and merging into the framework of benign tumors are to be classed as of simple irritative or of infective origin may possibly give rise to debate; provisionally I must refer them to the former class.

Another type of productive fibrosis, one that cannot satisfactorily be classed either as localized or generalized, is that due to inflammation of serous surfaces, a form including the fibroid thickening of serous superficies and organized inflammatory adhesions.

Besides these, there exist also generalized productive fibroses of inflammatory origin, which again may either be of infective origin (induced by bacteria or their products) or the result of continued non-infective irritation. The chronic interstitial pneumonia following upon subacute pleurisy may be cited among the former; among the latter, in all probability, the generalized interstitial fibrosis of so-called chronic parenchymatous disease, of which a good example is afforded by the condition of productive parenchymatous nephritis. But, as I shall have later occasion to point out, some forms at least of interstitial fibrous overgrowth are rather to be counted among the replacement than among the productive forms.

The local and general forms may merge, the one into the other. Thus, a liver presenting gummata may exhibit also well-marked generalized interstitial fibroid overgrowth; a kidney the seat of chronic tuberculosis may show the same; or again, in the inhalation pneumonias the deposit of foreign particles along the lymph spaces of the lungs may be so extensive and the growth thereby excited be so great that the organs present the characters of a generalized interstitial inflammation. Nevertheless, the distinction between local and general is in the main useful and not pedantic.

To turn now to the replacement fibroses; among these we can distinguish certain well-defined types. All may in truth be termed cicatricial, but it may be well to restrict this designation to the ordinary surgical cicatrix, to the connective tissue developed after breach of continuity in a part. Speaking broadly, it may be said that every such breach of continuity results in the destruction of a certain number of cells, and that in the absence of infective agents the new connective-tissue formation maintains a definite relationship to the amount of previous destruction, never exceeding it. Very closely allied is the development following upon the complete and sudden necrosis of all the elements of a tissue; of this, as previously hinted, a most satisfactory example is seen in the healing of a simple infarct.

¹ Delivered before the New York Pathological Society.

If we, following what is not unusual nowadays, regard the blood as a tissue, the organization of thrombi must be placed under the same heading of fibrosis following tissue necrosis; if we are more conservative in our employment of the term "tissue," we must regard the gradual substitution of the coagulated and necrosed blood by fibrous tissue as a closely allied phenomenon, namely as a fibrosis occurring in and replacing a necrotic mass.

Associated with these we can recognize two other forms. I would not insist upon their separation, but there is a slight difference in their mode of origin. In the one the essential cause of the death of the cells is local, from impaired nutrition, in the other the nobler elements of the tissue undergo atrophy and death irrespective of local conditions. The two forms may be termed dystrophic and atrophic respectively.

Of the atrophic I have already furnished an example, namely, the sclerosis following degeneration of ascending or descending nerve tracts. Of the dystrophic the heart furnishes the most frequent examples, though I am inclined to regard much of the fibroid change seen in the senile kidney as of the same nature. As M. H. Martin¹ was, I think, the first to point out explicitly, and as Weber² has shown in a very careful research, where there is an "obliterating endarteritis" of the coronary vessels with overgrowth of the intima and consequent diminution of the lumen, there must result a diminished nutrition of the area supplied by each affected artery or arteriole, and as these are of the nature of end arteries there is developed no satisfactory collateral nutrition. The result affords a very striking picture, more especially if the most frequent seat of the change be examined, namely, one of the papillary muscles of the left heart. In these the fibres run longitudinally and so also, entering at the base, do the nutrient arteries, and the condition is so common that I have never had difficulty in obtaining material for my class in morbid histology. In a typical fairly advanced case in transverse section of the muscle, the arterioles with thickened intima are seen cut transversely; around each is a zone of fairly healthy fibres also cut transversely. Passing outward from the artery these give place to fibres that present atrophy and pigmental degeneration with intermingling of new connective tissue, while the outer zone of supply of the arteriole is represented by a ring of clear, transparent fibrous tissue with relatively few nuclei and here and there the last remnant of a degenerated muscle fibre. This, I may remark, is but one form of cardiac sclerosis. It would be difficult to find a more demonstrative case of this dystrophic replacement fibrosis.

But while thus we are able to recognize examples of the uncomplicated occurrence of one or other form of inflammatory fibrosis, and while I hold that it is useful to us both as students of medical science and as practical physicians and surgeons to seek to analyze the nature and character of every morbid change, it has to be admitted, if we look honestly at things as they are, that case after case presenting itself to our notice cannot possibly be docketed and pigeonholed under one heading. Time and again we come across what can only be classified as mixed forms of the conditions already indicated, not to mention mixture of these with fibroid conditions which I have still to take into consideration. I can only urge that it is well to strive to cultivate our garden and not to allow our ideas of chronic inflammation to continue a riotous and tangled growth. Only by such cultivation can we hope to gain good fruit.

It is when we come to study the chronic inflamma-

tions affecting glandular organs that our great difficulty begins in comprehending the essential nature and causation of connective-tissue growth. Let us take the commonest case, namely, that of continued parenchymatous inflammation. Here the first obvious disturbance in the tissue is an affection of the glandular cells. With this there is an accompanying congestion of the interstitial vessels, and this gives place eventually to a condition in which the collections of gland cells are separated from each other by increased connective tissue, while coincidentally the gland cells themselves show signs of atrophy. Two conditions might produce this picture: either the atrophy of the gland cells might be primary and the increased fibrous tissue an indication of replacement fibrosis; or, on the other hand, the picture might indicate, as is usually held, a productive interstitial fibrosis with the malnutrition and atrophy of the gland cells as a secondary consequence of irritation, impaired nutrition, and pressure exerted by the new-formed tissue combined. It is only by a very full and cautious observation that it is possible to arrive at a decision in any given case as to which form of fibrosis is represented and often, indeed, one is induced to take the middle course and consider both in operation.

If, for example, we study the various forms of cirrhosis of the liver, both experimentally and by histological examination of various cases, this difficulty is very forcibly borne home to us. We can occasionally, it is true, make out with certainty the existence of a productive fibrosis; thus we frequently meet with what appears to be the earliest stage of ordinary so-called alcoholic cirrhosis, in which we observe small masses of small-celled infiltration along the portal sheaths. The condition looks definitely productive; it appears to be an inflammation around the interlobular branches of the portal vein, and the cells in the immediate neighborhood of these accumulations show no very decided signs of degeneration and atrophy. We can, again, as is occasionally the case in early stages of biliary obstruction, find the bile ducts enlarged and dilated and surrounded each with new connective tissue, so that the picture given is that of a productive inflammation immediately around these ducts. We can also, more frequently than is usually recognized, make out signs of fibrous-tissue overgrowth around the branches of the hepatic artery; out of eighty-eight post-mortems performed during last year, I found this periarteritis to be well marked in six cases; but in advanced cases of ordinary cirrhosis of the atrophic type it seems to me more than doubtful whether malnutrition of the cells does not become an important factor and their atrophy be not followed by replacement fibrosis, rather than be the result of pressure and encroachment of the newly developed connective tissue.

In this connection it is interesting to note how the majority of observers who have attempted experimentally to induce cirrhosis of the liver have noticed changes of a degenerative character in the hepatic cells as a first effect of irritation rather than productive inflammation in the interstitial substance. This, of course, is what might be expected, the nobler cells of the tissue being the more sensitive. I merely draw attention to it because it is so common to regard hepatic cirrhosis as primarily an interstitial disturbance. I do not wish to give the impression that this may not be so in certain cases; very frequently, I feel as sure, it is not. I need but remind you how strongly the recent studies by Flexner³ uphold this view.

Here I may briefly refer to certain studies which have occupied me during the last two years upon the causation and nature of a very remarkable disease

¹ H. Martin: *Revue de Médecine*, May, 1881.

² A. Weber: "Contribution à l'Étude Anato-mo-pathologique de l'Arterio-sclérose du Cœur," Paris, Steinheil, 1887.

³ Flexner: *Medical News* (Phila.), ii., 1894, p. 116.

affecting the cattle in a limited region of Nova Scotia, the so-called Pictou cattle disease. I do not wish here to publish a detailed and circumstantial account of my observations, for to do so would not be just to Professor Welch, to whom I have promised my completed paper upon the subject. I may, however, repeat what is stated in my reports to the Dominion government, namely, that the disease is of an infectious nature and due to a minute bacillus, characterized, as are so many of the pathogenic micro-organisms of lower animals, by an intense polar staining, so that frequently it has the appearance of a diplococcus rather than of a bacillus.

The disease is apparently of slow onset; the affected cattle eventually suffer from an abundant dark-colored diarrhœa, present a moderate amount of ascites, fail to give milk, and then the end is ushered in either by a condition of violent excitement or by progressive muscular weakness.

At the post-mortem the most characteristic features are the ascites, a remarkable submucous œdema of portions of the intestine (I have seen similar submucous œdema in cirrhosis of the liver in man), enlargement of the abdominal lymphatic glands, and a very extensive cirrhosis of the liver. It is in the lymph glands and the hepatic cells that the bacilli are present in greatest abundance.

The cirrhosis is generalized and of the pericellular type, and if the livers from a large number of cases be examined the earliest stages would appear to be those of swelling and vacuolation of the hepatic cells with great irregularity in the size of the nuclei. There may be great congestion of the hepatic (venous) capillaries, but this is unaccompanied by any notable small-celled infiltration. Following upon this stage of swelling, the hepatic cells undergo atrophy, sundry lobules and portions of the liver showing the process at a more advanced stage than do other portions. And this process may be so extensive that over large areas of the organ only isolated liver cells or clumps of three or four degenerating cells are to be recognized. With this the organ is not diminished, indeed the edges often tend to be slightly rounded and full; there is replacement of the degenerating cells and lobules by a delicate somewhat œdematous connective tissue. A characteristic of this new tissue is the relative absence of the ordinary signs of productive inflammation in the shape of small round cells. Of these there are a few, but very few; more frequent are small irregular cells, evidently degenerated liver cells and others of the "spider-cell" variety, with fairly numerous delicate processes.

In short, the impression gained by studying numerous sections obtained from many animals dying in different stages is that there is here a primary irritation or overstimulation of the hepatic cells by the bacilli, followed by an atrophy of the same and coincident replacement fibrosis. I will not say that this replacement fibrosis is the only form of connective-tissue hyperplasia present in these cases; there are occasional indications of productive change. But it is, I feel assured, the main form present.

This generalized pericellular cirrhosis is, of course, not strictly comparable with the more usual forms of hepatic cirrhosis met with in the human being. Its interest lies in this, that occasionally, more especially in children, we observe a curiously similar condition of the liver without any clear evidence of syphilis, and in children also the victims of congenital syphilis, even as to a less extent in adults presenting tertiary syphilis, we are apt to meet with a more or less extensive pericellular cirrhosis. In such cases it may well be that the cirrhosis is of like origin, due, that is to say, to the direct irritation of the hepatic cells by pathogenic bacteria or their products, to the atrophy

of these cells and their replacement by delicate connective tissue.

Thus far, therefore, we have been able to recognize the following forms of fibrosis of inflammatory origin:

- A. "Productive" fibroses.
 - (1) Localized $\left\{ \begin{array}{l} \text{focal.} \\ \text{capsular.} \end{array} \right.$
 - (2) Serous and adhesive $\left\{ \begin{array}{l} \text{local.} \\ \text{general.} \end{array} \right.$
 - (3) Interstitial.
- B. "Replacement" fibroses.
 - (1) Cicatricial.
 - (2) (Post)-necrotic.
 - (3) (Post)-atrophic.
 - (4) (Post)-dystrophic.
- C. Mixed fibroses.

But this classification does not nearly include all the examples of connective-tissue overgrowth and sclerosis occurring in the organs of the body.

One further group of cases may at first sight appear to be sharply defined, namely, the group of the true fibroid neoplasms, the fibromata proper. Nevertheless, a study of the forms usually included in this group reveals the fact that there has been in the past not a little confusion as to what constitutes a fibroma, and an attempt to classify the various forms cannot but lead to the conclusion that the line separating inflammatory new formation from fibroid neoplasms can be drawn only with a cautious hand.

As I have pointed out, one result of irritation may be overgrowth of connective tissue. Ordinarily this appears to be not greatly in excess of the needs of the injured area, nevertheless at times it exhibits itself greatly in excess of these needs. When infective agencies interfere with the normal course of cicatrization of a wound and the healing becomes delayed, when, in short, superadded to the normal tendency for fibrous tissue to be developed so as to repair a wound there is a stimulus to connective-tissue proliferation from the presence of bacteria and their products, then it would appear that fibrous tissue may be developed in excess of the requirements of the part. This "false" cheloid, it is clear, originates primarily after inflammation, and we may have every gradation from what may be regarded without second thought as redundant cicatricial tissue up to what, from its continued and very extensive growth, it is difficult to regard as other than a frank neoplasm. Another form I have already referred to, namely, the "spontaneous" cheloid developing where there has been no breach of continuity of the tissues. On this continent among the colored population (and the negro appears to be peculiarly prone to be affected) cases have been recorded in which the new formation has attained enormous proportions.

As an example of so-called spontaneous cheloid let me here briefly describe the case already referred to, studied by Mr. R. Martin, for it throws light upon sundry important features in this class of tumors. The patient was a French Canadian girl, aged twenty, who had always been healthy until about four years ago, when she noticed a very small growth which looked like a little pimple on her left shoulder. This gradually enlarged and in about a year began to be painful, causing sharp, stinging pains. At the end of two years it was two inches long and three-quarters of an inch wide, and was then removed by the knife. About three weeks after the operation it recurred and became as large as before. An operation four months later was again followed by a recurrence. Three or four months later it was removed "by means of a plaster." It has never returned, but there remains a very large cicatrix, larger in fact than the original tumor. The patient was free from any further growths until about a year ago, when another small pimple appeared on the outer side of the right arm

just above the elbow, which gradually grew larger until in April, 1895, it was one inch long, about a third of an inch wide, and elevated above the skin. The edges where it passed into the surrounding skin were irregular and claw-like. On further examination another similar tumor was found on the back, and when the skin was made tense in several places, principally on the outer side of the right arm, clusters of flat, small round cicatricial spots were noted, of a white and glistening appearance. Each cluster contained about four or five spots. Upon relaxing the skin these clusters were unnoticeable. In July the clusters had all disappeared and there remained only the tumor on the back, which was also diminishing in size. At this time needle scratches were made on the left arm. When seen again in September, 1895, little nodular lines of cicatricial aspect were to be observed corresponding to the previous slight scratches caused by the needle. It may be added that microscopical examination of the tumor removed from the arm in April presented all the characters of true cheloid.

Here, then, we have a case apparently of spontaneous cheloid, in which nevertheless the subsequent history, results of operation, and of experimental slight cutaneous disturbance show that the fibroid hyperplasia was to be induced by injury, so that presumably the primary growth had a similar origin, not improbably, as in certain recorded cases, from an acne pustule. The case affords an example of what might very easily in its earlier stages have been classified as spontaneous cheloid.

In fact, from this case and from a study of the literature of cheloid, I am led with Jonathan Hutchinson to doubt whether the conception of a spontaneous cheloid is possible or consonant with facts.

Thus, it can be shown that in those exhibiting a tendency to the disease—those in whom cheloid masses already exist—a minimal irritation as, for example, the scratch of a pin, may induce the subsequent appearance of a mass of subcutaneous fibrous tissue in the region. Where this is the case it is difficult to deny that the condition originates as a productive inflammatory fibrosis, and the fact that at times some if not all of the multiple nodules undergo absorption and disappear (as happened in Mr. Martin's case to which I have already referred) is against regarding the condition as typically fibromatous. It is equally difficult, in fact impossible, to maintain that a mass of new tissue, which occasionally attains to the weight of a pound or more, projecting from the head or trunk is an example of inflammatory fibrosis. It is difficult to see where the line is to be drawn, unless, as I have recently urged in an address before the Medico-Chirurgical Society at Montreal,¹ we recognize that in inflammation the new-tissue formation ceases with the removal or cessation of the irritant, whereas in neoplasms the cells, having once commenced to proliferate rapidly (whether as the result of chronic inflammation of moderate intensity or from other cause or causes), gain a habit of growth and continue to proliferate independently of any due stimulus. Assuredly, in these multiple cheloids as in the cicatricial forms growth of the tissue is continued after the irritant has ceased to be in evidence, and consequently I am bound from their course to classify them as among the fibromata—as fibromata of inflammatory origin.

I am not prepared to do the same with another form, the so-called "lamellar fibromata," whereof the most frequent examples are to be encountered as dense, sharply defined, whitish nodules and small plaques upon the surface of the spleen. So far as I have been able to follow their development, these appear to be examples of pure and simple inflammatory

growth. I can see in them no evidence of continued growth independent of injury or irritation.

Besides these two forms we have the group of typical fibromata, isolated, sharply defined neoplasms of in general slow growth. While among the cheloids we can postulate an inflammatory origin, in these we cannot as yet venture to assign a satisfactory causation. Nor is the time quite ripe to make a positive statement concerning the massive interstitial tissue occurring in sundry mixed tumors, in fibrolipomata, fibromyxomata, scirrhus cancer, etc. Studying these and comparing the outer border with the more internal parts, I gain the impression that in many cases we have, as in cheloid, to deal with a productive inflammatory fibrosis which merges insensibly into neoplastic incontinent growth. This is my impression, and I dare make no more definite statement.

Thus we can divide the forms contained under the title of fibroma into:

- A. Pure or true fibroma.
 - (1) Of inflammatory origin (most if not all examples of cheloid).
 - (2) Of undetermined causation (typical hard and soft fibromata).
- B. Mixed fibroma, benign, cancerous, and sarcomatous (admixture of fibroid overgrowth with overgrowth of other tissues).
- C. False fibroma (due to simple productive inflammation, e.g., "lamellar" fibromata).

HYSTERICAL TETANY OR TETANOID HYSTERIA.¹

BY GRACE PECKHAM MURRAY, M.D.,

NEW YORK.

As no definite anatomical lesion has been found for either tetany or hysteria, one gropes in the dark in regard to these two diseases and can classify and distinguish them only by groups of symptoms. Hysteria is a protean disease and tetany is a manifestation of protean conditions, so much so that many recent writers, among whom are Gilles de la Tourette,² Raymond, and Zaldivar, regard nearly all cases of tetany as manifestations of hysteria; no matter in what manner produced. Others who do not go so far say that it should be considered as a symptom and not as a disease. If such is the case, that tetany is only a symptom of a disease, and, further yet, only a manifestation of hysteria, the title tetanoid hysteria would be a correct one, and yet as far as I can find the condition which I am about to describe has never been called by this name, though Raymond has given it the name of hysterical tetany (*tétanie hystérique*), which has been since used by other observers. The list of names which have been employed for this condition, since it was first described by Stanheim and Dance in 1830, is a commentary upon the confusion which has existed in regard to it.

Dance called it *tétanos intermittente*; Murdoch, *retraction musculaire spasmodique*; Constant, *contracture essentielle*; Trousseau, *contracture intermittente des nourrices*, *rheumatismæ tetanille*; Corvisart, *tétanie*; Delpech, *spasmes musculaires idiopathiques*; Marfan, *pseudo-tétanos*; Eisemann, *brachio-tonus rheumaticus*; Jules Simon, *contracture essentielle des extrémités*; Raymond, *tétanie hystérique*. To such a group of names it would be unwarrantable to add an-

¹ Paper read before the New York State Medical Society, Albany, January 29, 1896.

² Hysteria embraces a great part of the contractures of the extremities, benign or severe, called tetany. In France the affection is rarely anything but hysterical. In the last ten years there has not been in Salpêtrière, in the service of M. Charcot, any attack of tetany that was not hysterical, except possibly one ("*Traité Clinique et Thérapeutique de l'Hystérie*").

¹ "The Habit of Growth," *Montreal Medical Journal*, February, 1896.

other. The day will doubtless come when the true etiology, that is, the pathological conditions of hysteria and tetany, will be discovered, these enigmas will be solved, and then there will be a new and enlightened rechristening, in which possibly none of these names will be used except to illustrate the pagan condition in which they exist at the present time.

The condition to which these numerous names have been given and which they describe presents a group of symptoms which, though differing in degree, remain most constant in the salient features, that is, the contraction of the muscles, which are held in tonic

occurred after some overexertion or some excitement or mental worry. They were preceded by sickness of the stomach and headache. Some hours before the attacks she would be pale and drait, and there would be twitchings of the flexor muscles of the hand and a feeling of numbness. With these warning symptoms, by rest and by the use of aromatic ammonia and stimulants she was able to ward off the attacks, against which she fought with great determination. When the attack culminated the head was drawn back, the fingers were flexed, the hands thrown somewhat back upon the wrists, the thumbs folded under the fingers; the feet also would be drawn backward, and the toes flexed. The pulse dropped from normal to between 50 and 60 per minute. Once or twice, when I have seen her in these attacks, there was some suggestion of catalepsy, the hand and fingers retaining the tonic spasm, but the arm taking and retaining for a short time the position in which it might be placed. The tonic contractions lasted from ten minutes to an hour. How long they would continue without remedies I could not say. Inhalations of aromatic ammonia, as well as taking it internally, would shorten the spasms, and sometimes would prevent them altogether.

CASE II. was that of a young girl who was about sixteen years of age at the time of the first attack,

FIG. 1.—Hysterical Contraction of the Hand. (Gille de la Tourette.)

spasms for a time varying from a few minutes to hours and even to several days, the contracting group of muscles varying in number, usually beginning with one or more of the flexor muscles of the extremities and extending to those of the trunk.

According to the extent of these contractions, Trousseau divided the cases into three classes: benign, medium, and severe. Singularly enough it has been my fortune to meet three cases illustrating these three conditions and also in the order of their gravity. Before further analyzing the symptoms, the disease will be better understood by illustrating them with these cases.

CASE I. was that of a married woman, about forty, who was of a very neurotic type and of a neurotic inheritance, constitutionally anæmic. She first came under my care for endometritis following a miscarriage and an ante flexion, which were corrected. She had these spasmodic attacks at varying intervals since she was a young lady, but they did not assume

FIG. 2.—Hysterical Contraction of the Hand. (Gilles de la Tourette.)

a serious nature until the death of her father, when they became more severe and frequent. They usually

FIG. 3.—Hysterical Contraction of the Feet. (Charcot.)

which came on after a severe mental shock and an operation on one eye for strabismus. She recovered from this attack, when she had another two years after a fatiguing and exciting journey abroad. As the attack occurred near her menstrual period the question of uterine disease arose, but there being no symptoms pointing to that I did not feel that an examination of the young girl was justified. She was very anæmic and neurotic, and of a neurotic inheritance. Her mind was always clear, she was sensible, and very much mortified and chagrined by these attacks, which she would try to escape by every means in her power. Before they came on her face was pale and wore an anxious, distressed look, her eyes were dull and had a peculiar appearance, and she felt a sense of faintness in the epigastrium. There was a weakness of the lower extremities, so that she was unable to stand, the fingers were flexed and closed over the flexed thumb, the head was drawn back and the back arched, the toes were flexed and the feet extended on the leg. The contractions were much more rigid than

those of Case I. The attacks, which were very painful, varied in severity and length from a few minutes to an hour. The first attack, in which I did not see her, lasted twenty-seven hours, and the contractions would recur at intervals if there were any excitement to bring them on. The greatest irritability of the whole nervous system prevailed. If there was a slight sound or a gentle touch, even on the bed, the patient would

FIG. 4.—Hystercal Contraction of the Toes. (Charcot.)

affection, the spasms. When the spasms are coming on, for a variable time before she has a cold numb feeling with an intense aching and a stiffness before the drawing begins; sometimes there is a sharp darting pain up and down the spine. The spine is always sensitive to the touch, but just before an attack it is much more sensitive. Those about her can tell when an attack is coming on by the distressed look in her eyes and the stiff way in which she holds her head. She says the pain begins at the end of her spine and then the fingers begin to pull, and then the tongue, and then the hair, as if it were standing on end; and so the contractions spread until the fingers are flexed on the hand, the hand on the wrist, the hand on the forearm, and the arm itself is drawn tightly to the chest by the action of the pectoral muscles. The head is drawn back as far as possible. She has always been lying on her side when I have seen her in these attacks. The knees are drawn up on the body, and the feet extended with the toes flexed tightly (see Fig. 6). She complains of a choking sensation.

start and jump. Two years later, after the funeral of her father, there was a return of the trouble. At this time the attacks were preceded by periods of an hour or more of immobility. She was unable to stir or to speak, but was conscious of what was going on about her. She was relieved in each instance by taking a rest cure and by the use of electricity and sedatives.

CASE III. was the most severe of all. The patient was a woman who is now sixty. She was the fourth child of ten, whose mother was very much overworked. The patient was very nervous; as a child she had nocturnal terrors from which she would awake with a shriek. When she began to grow she had pain in her back. She is very tall and at thirteen had attained her growth. At eighteen she saw the gentleman to whom she was engaged killed by being thrown from a horse, which was frightened by a flash of lightning. For days after she was unconscious or in a delirium, always saying that there was something the matter with her back. When she first began to go about after that illness she had two or three of these attacks of contraction. Although she had more or less pain in her spine, she had no more of them until the third day after her mother's death seven years ago. She had the menopause twenty years ago, at which time appeared the most intractable irritation and itching of the vulva, for which Dr. Emma Ward Edwards, of Newark, whose patient she has been for years and to whom I am indebted for the case, had tried everything possible. As a last resort the nymphæ were amputated but without giving relief. All the parts had undergone a very great atrophy, except the clitoris, which was very prominent and enlarged. The mucous membrane was very much altered in character, thickened, and hardened. This was benefited by the operation. I do not think that the pruritus vulvæ has had any connection with the nervous

FIG. 5.—Contraction of the Hand showing Trousseau's Main d'Accoucheur. (Buzard.)

Her face is purple and the temporal veins are very much swollen; the pulse remains normal and there is no feverish movement. It is impossible to describe the tension and rigidity of the muscular contractions. The case is unusual in the extent of muscles involved. It is seldom that the spasms invade the trunk muscles. In this case not only the laryngeal, facial, and thoracic muscles are involved, but also the muscles of the perineum and the sphincter vaginæ.

The patient has had attacks of unconsciousness lasting for some time. I never saw her in one of these and cannot say what relation they hold to the rest of her trouble. She had also an attack of somnolence which lasted two or three days. It was impossible

for her to keep awake for any length of time. If she attempted to dress she would fall asleep. Previous to that, as well as since then, she has had insomnia.

She complains of having most of the time a feeling of confusion and bewilderment if she makes a quick motion or has any excitement.

I have spoken in the other cases of the clonic spasms of the muscles of the hand, more or less rhythmical, which precede the attacks. This patient has almost constantly a rhythmical spasm of the flexors of both hands, as well as the pronators. When talking or excited, these spasms, which average about sixty or seventy a minute, are increased in force.

The patient is thin and very anæmic.

She showed the same irritability of the nervous system by her sensitiveness to touch and sound, as was shown in a degree in Case I. and to a greater extent in Case II. During the attacks the eyelids were constantly moving with a tremulous motion. In the other two cases they were closed. The pupils presented no unusual appearance.

All writers speak of the prodromata of the attack.

spasms of the flexor and pronator muscles of the hands and forearms were present before the tonic contractions of the muscles took place. Some cases are recorded where clonic spasms have followed the attacks, but none that I know of where the clonic spasms preceded the attack. The clonic spasms were frequently present in Case III. when the patient was talking and excited. When no attack was pending there was a regular rhythmical myoclonus of sixty to seventy beats per minute.

Trousseau and others speak of the contraction of the muscles of the hand drawing the fingers together so as to make a hollow cone of the hand, the hand of the accoucheur (see Fig. 5). In all of my cases the fingers were flexed on the hand. Some writers speak of the contractions of the muscles as always bilateral.

The study of the pulse in these cases is of interest. In Cases I. and II. the pulse was slowed to between 50 and 60. In Case III. the heart did not seem much affected, the pulse being about 80. In many cases reported the heart's beat is greatly accelerated, due, it was said, to the asphyxia caused by

FIG. 6.—Schematic Representation of Tetanoid Contractions of the Muscles in Case III.

There is a feeling of malaise, and a general pallor, headache in a great number of cases. None of my cases had the prickling sensations described by Trousseau and by others. Some have a numbness and rigidity. My patient in Case III. had always a feeling of cold and rigidity in the back. In all cases there is a premonition of the attack some time before it occurs. A peculiar leaden look was seen in the eyes of all my patients.

Before the contractions take place there is a sense of weakness which in many cases makes it impossible for the patient to stand. The contractions of the muscle groups follow in different order in different cases, but generally the flexor muscles of the hands contract first, then those of the feet, and then the larger flexor muscles of the upper and lower extremities. In Case III. the spasms generalized so quickly that it was impossible to tell which muscles contracted first, the intensity and rigidity continually deepening until the climax was reached. In studying my own cases as well as those reported, my opinion is that the contracting spasms run along the lines of least resistance; for instance, the fingers are flexed first, the flexing of the fingers being the most frequent voluntary act of the whole body. Opisthotonos is more frequent than emprosthotonos.

The contraction of the extremities is well-nigh universal, therefore it is the name which has been most frequently given to the disease. The extreme rigidity of the muscles should be seen to be realized. Nothing voluntary could approach it in the severe cases. As a writer has described it, the patients were as stiff as if made of iron.

The trembling of the eyelids is frequent. Schultz speaks of fibrillary contraction of the thenar and hypothenar eminence. In all of my cases clonic

contraction of the muscles of respiration. The face is often greatly congested and the veins swollen and tortuous. The slowing of the heart, which has not been noted heretofore, that I am aware of, is due I believe to a spasm of the heart muscle, which, were it to become very rigid, as in the case of the voluntary muscles already alluded to, might occasion a fatal termination of the disease. This and asphyxia due to spasmodic constriction of the lungs might occasion a fatal termination, the latter being the only cause of death known to hysteria. A fatal termination of hysterical tetany has not been recorded. The prognosis as regards recovery is also good.

The temperature is generally normal. If fever is present it is due to some other cause. Jaksch, who has made tests on thirty-five cases, reports that nine out of the thirty-five had subnormal temperature. In the others there was an increase above the normal. No systematic record of the temperature was made in the first two of my cases. In Case III. the temperature was below normal.

The great difference between these cases of tetanoid hysteria and other forms is the fact that the brain is undisturbed. The mind is clear, and the effort to control and throw off the attack is always intelligent and earnest. The pain from the contraction of the muscles is very great. Jaksch says there is great sweating in severe cases while the pain lasts. This was not present in any of my cases.

The electrical and mechanical irritability of the motor nerves in all these cases is greatly increased. Kussmaul, Benedict, Erb, Chvostek, and others have investigated this part of the subject thoroughly. I did not have the opportunity to do so in my cases. One could not expect any other condition to be present. The hearing of all three was greatly exalted; a

slight noise would either induce an attack or, if it were present, would intensify the contractions. The state was exactly similar to that of the frog which has received strychnine, as exhibited in physiological lectures.

Reference should be made to the so-called phenomenon of Trousseau, by which is meant the reproduction of the spasms at will by compressing the affected parts, either in the direction of their principal nerve trunks or over the blood-vessels so as to impede the circulation, venous or arterial. I regret not having observed whether this was present or not in my cases. Charcot has said that this symptom was not especially diagnostic, as such compressions would occasion contracture in patients of an hysterical diathesis, and he gave the name of diathesis of contracture to this condition. Weiss and Chvostek found that contractions could likewise be produced by drawing back the corner of the mouth and the angle of the nose and making pressure on the pes anserinus. But Hochwart found the same thing, though in a lesser degree, in patients not suffering from tetany.

In discussing these cases I cannot hope to have escaped from the confusion in which the whole subject is involved, for the reason that it has been for the most part approached from the side of tetany, which, as has been already said, is more of a symptom than a disease, since it occurs in a variety of morbid conditions. There is the tetany of infants and children; there is the tetany of epidemics, which Simon calls a "neurosis and an imitation";¹ there is the tetany which occurs from poisons ingested, as ergot, mercury, and lead, and arsenic; the tetany which occurs from the poisons generated within the body, the ptomaines and the poisons of disease, rheumatism, diarrhœa, constipation, typhoid fever, meningitis, and traumatism.

Notwithstanding all these different kinds of tetany, spontaneous or symptomatic, cases are very rare, and even those engaged in the study of nervous diseases alone may fail to meet a case in the course of years of practice. Dr. Crozer Griffith collected the cases of tetany of every variety that had occurred in America, and these numbered but seventy-two.

Because of the lack of positive knowledge of the pathological anatomy of the condition, the theories of the causation of the trouble are endless. The seat of the trouble has been located in the muscles themselves, in the nerve endings and in the nerve trunks, in various conditions of the spinal cord—softening, inflammation, or sclerosis, inflammation of the anterior horns, of the membranes—trouble in the medulla, in the cerebellum, and in the different portions of the brain. Whatever may be the cause, there seems to be a loss of the governing and adjusting power. Dr. Hughlings Jackson thought that it was due to the defective antagonism of the cerebellar influence. In health all muscles are doubly innervated by both the cerebellum and the cerebrum, there being a co-operation of antagonism between the two great centres. While the cerebrum innervates the muscles in the order of their action from the most voluntary movements (the limbs), to the most automatic (the trunk), the cerebellum innervates them in the opposite order. The cerebrum is the centre for changing movements and the cerebellum for constant movements. The theory is ingenious and plausible. I cannot help believing that the trouble is due to some generalized centric condition too delicate and subtle for us as yet to determine and not to any localized focal lesion.

¹ The history of the epidemics of tetany is illustrative of the hysterical aspect of the disease and forms a most interesting chapter, to which the limits of this paper forbid more than a passing allusion. There were epidemics in Germany in 1691 and 1717 affecting adults exclusively. Armstrong reports one in Hempstead in 1776. Rabaud reports an epidemic among children in 1856, and Maitrais, Regnaud, and Simon the epidemic among the school children of Chantilly.

In regard to the treatment it may be said that the spasms have been relaxed by chloroform, ether, aromatic ammonia, stimulants, applications of heat and cold in the form of baths and bandages, applications of ice to the spine. Pressure along the great vessels and nerve trunks supplying the parts is said to relieve the spasms of the muscles when present as well as to produce them. The recurrence of the trouble is prevented by all the means employed in hysteria and neurasthenia, such as rest cure, tonics, and galvanism.

SANITARY CARE OF MEN IN MASSES.

By MAJOR ALFRED F. SEARS,

CIVIL-SANITARY ENGINEER.

Introduction.—During our Civil War, one company in my regiment, of which the captain was a doctor of medicine, lost nine men by disease during the first six months in camp, while not one enlisted man died of disease in the sanitary engineer's company during the entire three years for which they entered the service.

After such a statement, I must explain before going further that this article is not an attack on the medico; is not dogmatic writing on medicine or hygiene; is not written to present or support a "system"; is not in the interest of any hygienic sect or school of medicine.

It is a simple note of more than forty years' experience in caring for the health of men in masses, in varying life and climate. Men young and old, aiming to be soldiers, in barracks for instruction; these same men massed on shipboard for transportation to the seat of war, and then, already graduated for duty, in camp on malarious islands of the southern coast; at work too, all through the poison-nights, knee deep in diluted mud of the Savannah River marshes. And again, laborers of the most degraded class, from hiding in city slums to escape the army draft of war times, carried in dirty crowds to work in Florida. Creoles, aboriginal Indians, and Chinamen, on railroads in the tropics, operating, building, and surveying. Such are the beings and circumstances of which this story treats.

As to the medicos, mine is the common experience. There is the black-coated owl, dull and dogmatic, who believes medicine a science; who never gets away from his formulæ and passes through life wondering at last how he has so often escaped the fangs of a grand jury. And then there is the man of common sense, who knows he is practising an art as imperfect as the brain of man. There is a doctor of medicine and a doctor of hygiene, both rated M.D., which reckons no difference between the two; an egregious error; one carries a baton for the service of the preserver of life, while the other trains his mortar in the ranks of the angel of death. One cares for health, the other for disease; and the thing cared for comes out ahead.

My personal condition curiously illustrates the difference in "medical" practice. I was born of parents healthy to robustness. When ten years old, a thin boy, long and growing, I suffered in the eyes a dreadful pain, with blindness threatening; and worse, because a doctor, fond of active practice and heroic, attacked the trouble with senna, blisters, and bleeding, determined on conquering though he pass over a dead body to the victory, which he would have done but that after three years of battling he died; to the last with confidence fighting. After that I began to improve; at twenty had all my height of five feet ten, but somewhat crooked; for my chest was sunken, shoulders stooping; I had hollow cheeks, goggle eyes, and was paler than one likes to see young manhood. But during the last four years of that time I had been a severe student, passing but three or four hours of any night in bed; and so the spring of 1847 found me seriously threatened with the New Englander's great enemy, consumption.

My ambition to be an architect had been surrendered, because the drawing board and heated office air combining, had come near confirming the old doctor's work, and now I was at civil engineering, with fair share of time in the open air exercising.

By lucky turn of fortune, I met a good physician, who refused to give drugs and told me the truth; it

was to keep out of doors all my duty would permit and sleep nine hours a night, letting ambition slide till I had life and strength to bear it. I followed his directions and they were simple, so that I grew erect and strong, and from thirty-three inches around the chest came to measure forty, since then risen to forty-four. The color came to my cheeks, good muscle my bones clothing. It was the simplest thing in the world. I but gave the lungs an even chance with the brain. When I walked out, I took in long breaths of fresh air, or such air at any rate as was going, and held it in as long as ever I could. In doing this I made no effort to throw my shoulders back as some proclaim, but exercised the abdominal muscles, drawing in the belly, the diaphragm thus raising.

Above all, I determined to live.

I said, "if I die of consumption it shall not be my fault." But it required two years of constant caring—two years in which I suffered pain and soreness in the lungs, while the half-closed cells were being torn open; and in the belly muscles, to unused effort now accustoming.

This was the beginning of a study and devotion to hygiene, since developed into the practice of sanitary engineering.¹

I. In Camps of Instruction.—Two distinct classes of men leave their homes for the enterprises of life: those who go and those who are sent. The volunteers, whether soldiers in barracks, inspired by patriotic public spirit, or ambitious students in commons, are stimulated by powerful impulses and sustained by a moral tone to which the conscript and the boy subject of parental authority are strangers. And yet in either case the moral influence surrounding the novice will be a prime factor in estimating his sanitary chances.

For as truly as the volunteer, soldier, or student is moved by a noble passion just so surely he demands a tender consideration to perpetuate his illusion, while the unwilling subject must be protected against the danger of his discontent. Much moral effect may be produced by showing due—even ostentatious—regard for the comfort, the physical surroundings of men.

In the summer of 1861, I took the nucleus of a company to the camp of instruction on Staten Island, where the men, preparing for incorporation in a regiment, were put into barracks—a building of rough boards lined with bunks and as cheerless as possible.

When autumn came, dysentery made its appearance in the camp and was treated by the surgeon of the regiment with astringent remedies for acute symptoms, but without the slightest regard to the men's diet or the cooking of the camp, or its potable water. This suffering was saved my company by attention to the cooks, that the white beans served in rations were properly prepared and also the rice and corn.

The water of that company was all boiled before the men were permitted to drink it, and, till they received their canteens, was kept in earthen monkeys and hung in a strong current of air, where rapid evaporation from the sweating, porous sides kept it cool.²

¹ The splendid sanitary results in the care of my Company, through which not a life was lost by disease among the enlisted men, during the whole three years for which they entered the service of their country, was due largely to the fidelity and intelligence of the lieutenants who had charge of it after I was detached—Hiram Farrand, of Vineland, N. J.; E. N. K. Talcott, of Jersey City, N. J., and Henry Trenor, of Brooklyn, N. Y.

² The London Queen published this year certain facts from Mr. Hankin's report concerning cholera in the East Lancashire Regiment, of value in the present connection. All six companies of the regiment drank water from the same well, filtered through the same filter. The cholera bacillus was found in the water after it had passed the filter, although it was quite free from any previous to filtering. The sand was proved, before the examining court, to have been taken from a condemned

But, more effective than this, was the attention given to men at night. In the early autumn months men fall asleep under but little covering. By midnight a change of temperature occurs, the air growing cooler and cooler, till, toward morning, it is almost cold. The phlegmatic, heavy man, solid sleeper, fails to notice the change and the surface of his body becomes chilled; a congestion supervenes. Toward morning he is turned out with bellyache, and then follows dysentery.

Company E was kept entirely clear of dysentery by the simple attention of its captain. Every midnight he went through the barracks, accompanied by a sergeant with a lantern, and covered with a blanket the men he found uncovered. The effect was twofold; we escaped disease; but, also, the men became not only the soldiers of their company, they were the friends of their officers, the children of their captain.

The most difficult duty of an officer in a great volunteer army is to secure general cleanliness among the men. This must be insisted upon. In all masses of men, so mixed in character as the soldiers of a war are, there are sure to be negligent fellows requiring hard nudging to make them bathe as often and as thoroughly as they should. In such an army there will always be trouble from this cause, unknown to the routine life and discipline of the regular army in peace.

There must be assiduous perseverance in the personal inspection of the men. On Sunday-morning inspections, make them bare one foot and expose the throat and breast. It is the necessary protection of all against the vermin breeding of the filthy. The simple knowledge that such inspection will be made secures the object, for no man, no matter how low he may be, can stand the abuse of his fellows or the public rebuke of the inspector, which his comrades are sure to make many times worse than the officer's scathing.

Men in masses, even so small as surveying parties in forest camps, will become lousy if not watched.

I have been guilty of some lawlessness in the face of a brutal regimental surgeon, for the sake of the men. It happened that when the company had nearly its quota there came to it a long, thin, undeveloped specimen of patriotic young manhood from New Jersey, who, utterly unfit for a night's absence from his mother and physically unsuited to a soldier's life, had been filled with fervor in his country's cause by the newspapers of the great city and the non-combatant orators of his neighborhood, had enlisted under the State's authority, and had come to pass his first night in the barracks of a camp of instruction. He stood the afternoon and evening with good courage, but by morning his backbone had melted out of him. When I entered the men's quarters in the early dawn he was sitting on the side of his bunk, crying violently, and some of the younger men near him were also in tears. He was a wretched physical being, and I hoped to be rid of him with a surgeon's certificate. But our doctor had been given no human sympathy, little moral sense, and, as it eventually proved, no proper ability for his position. He abused the poor wretch, found him suffering only with nostalgia, and sent him back to his quarters, where he had already infected the young men with his weakness. The poor fellow came running to me and fell on his knees, howling in agony at thought of spending his life away from his home. In the morning trip to the New York Arsenal, where the recruits were transferred from the State to the federal service, from which desertion would not

be an easy thing, the "man" got away on Whitehall Street at the corner of Front Street. The doctor missed him at Beaver Street, but the case was beyond his reach, for the fellow's legs were long and his marrow inspired. The war lasted no longer and a life was saved by his desertion. When I returned to camp that evening the men were all cheerful and glad to be rid of their weak comrade. He was the worst subject of his kind I have ever encountered, and by his presence would have demoralized a half-dozen men.

II. On Shipboard.—Some of us in the Department of the South often wondered if we were soldiers or sailors, so much of our time was spent on shipboard "waiting" to do something.

It is here the officer who cares for his men has some rest from a part of his trials.

Our troops were put on board ship for transportation to some other part of the coast, and kept there several weeks at a time, with no provision for hospital service.

Often the ship's captain knew nothing of his destination nor when he would receive orders to sail. The men were crowded and the sick were mixed with the well. Yet, although this life occupied so much of the first year of the war, I never knew a death on shipboard. The men were seasick and homesick. They suffered that uncertainty which is an affliction to all intelligent beings, used as the subordinate parts of an unreasoning machine. But they managed to live till they got ashore.

Such experience leads one to inquire if there be as much "infection" in "contagious" disease as mankind is generally disposed to find.

There is good reason for the condition as we find it. American ships are marvellously clean; they are well ventilated; the hours of meals are as regular as the ship's watch; the food is well cooked by skilled men employed for that purpose; the drinking water is distilled; there is no exposure to miasm nor to the inclemencies of the weather.

But we had trials. Every time a man had a trifling fever the surgeon pronounced it "typhoid." For a time this served to scare the men and raise faith in a doctor so marvellously successful with that dread disease. One really serious case of a young lad—a drummer—was taken to my stateroom, and by watching the attentions of the doctor as well as the symptoms of the patient the boy pulled through.

III. In Camps in the Field—Hilton Head.—In no situation of men is so intelligent and assiduous care demanded as in field camps on a stranger soil.

We were Northern men in our first camp on the field, at Hilton Head Island, on the coast of South Carolina. The soil being sandy, the position of the camp was salubrious. But there was a great difference in the sanitary conditions of the various companies of our battalion, situated side by side and composed of men of similar circumstances in life.

The men of Company E were encouraged to take advantage of every means of increasing their personal comfort. Thus, they found a rick of rye straw in the barnyard of the estate on which they were encamped, and every man had a good bed. One morning, when these luxurious bundles of straw were undergoing their daily airing, the colonel of the regiment, an inexperienced martinet of the splurge variety, forbade the indulgence. He was going to have his men act as soldiers, so the straw was thrown out in accordance with his order, but was immediately returned to the tents and never again mentioned.

Let the men under your care suffer discomforts only when they cannot be avoided. Everything helping men to enjoy life in a soldier's camp in time of war, strengthens them for the terrible days and nights inseparable from the duties of the active campaign.

bank in which the bacilli were developed. The extraordinary feature of the case, however, was that one company escaped the disease which afflicted all the others. At the same court examination it was proved that the water of this company only had been boiled before it was given to the men.

How much time we had to spend in loafing! in the absolute loss of one end of our eternity! This was unendurable; so at last we undertook in Company E a school in some of the field work of the engineer. Men were detailed to the bush for material and the company street became a busy scene of manufacturing. We took the time for making fascines and gabions. We had for instructor a sergeant—Richard Gowers—who had been in the Crimean campaign and was an adept in this class of work. This practice stood the company in good stead, and for the time kept them cheerful. It was good for them to go into the woods; and good to cut up and trim the sweet, green stuff into useful forms.

At this camp the first lieutenant of the company was taken ill with "typhoid," just as we were ordered away and so forced to abandon him to the doctor of the regiment. It was his misfortune to be a commissioned officer and receive special attention from an ignoramus. He died, and his was the only death from disease in Company E during the war.

Daufuskie Island and Savannah River.—The campaign against Fort Pulaski was begun from the northwest side of that work, the operations being under the command of Gen. Egbert L. Viele. A battery of Parrot rifles with flanking howitzers—Fort Vulcan—was erected on Venus Point in the Savannah River, the site being a dune on the south side of a little marsh island subject to inundation but covered with tall reeds that afforded a mask for work.

Here the men worked night and day, often knee deep in mud and water. Poles were cut on Daufuskie Island, where the camp of the troops had been established, and sand bags filled at the same place to be at night transported to Jones' Island; the poles for a sort of roadway and the sand bags for the foundation of the gun platforms.

Each forenoon at eleven and in the afternoon at four o'clock, the men of the fatigue parties were entitled to a ration of whiskey. The men of Company E did not get it. In lieu thereof, by the cordial permission of General Viele, they received extra rations of food; and so all fatigue parties of Company E went to their work with canteens of tea or coffee, as they preferred, and an extra allowance of cooked meat and bread for their lunches.

And here it seems proper to declare my uncompromising opinion, as the result of a long experience in dealing with men, that the time has never occurred when the regular ration of whiskey is other than a danger to the health of those who receive it and a menace to the good order and discipline of the camp. Thirty odd years ago I was not so sure of the fact, and there were times, therefore, when I surrendered to the orders of the surgeons and gave whiskey and quinine to the men. When some old hulk had been kept afloat in whiskey a term of years, it would have been cruel to cut off his dram, but in the case of young men coming under my charge from the tender care of home, I felt then, as I do now, that to have taught them the use of alcoholic stimulants by administering this stupid prescription of incompetent medicos would be a responsibility no rational (not to say benevolent) man should dare assume.

In this connection it is a duty, as it is a pleasure, to mention with profound gratitude my indebtedness to the assistant surgeon of my regiment, who had been detailed to duty with my detachment. Dr. Charles Mudge, of Ontario Co., N. Y., put conscience into his work as well as skill. He even joined with the officers in what would be considered an unprofessional act by the rigid sticklers of the schools, sending to New York for a lot of what is known as "composition powder," called by the practitioners of the Thompsonian school a "diffusive stimulant." It is largely composed of

bayberry bark and ginger, and has long been known as a useful and convenient remedy in surveying camps; it is invaluable in camp fevers, colds, and stomach troubles or diarrhœa, if used immediately on the appearance of the warning symptoms. With this remedy we avoided the use of whiskey and quinine and were able to close the mercury jar. In short, with this simple remedy we prevented disease.

When a man returned to camp at night chilled, and suffering what the homœopathists call "anguish," we clad him in dry clothes, gave him a generous hot drink of composition tea and put him to bed on clean, dry straw. The case was rare, when such a man was not ready for duty the next morning. He rose, sponged off his body, put on dry clothing, and went out to his duty as if he had never felt ill. The men declared Dr. Mudge a trump and hoped they would never again see the chief surgeon of the regiment. One man did his work with pills, the other with conscience.

When possible, the commander should select for a field camp a grass-grown sod, which is to be left unbroken. This was the good fortune of our camp on Daufuskie. The men were carried in row boats to Jones Island for work and returned to Daufuskie for their sleep.

Fernandina on the Coast of Florida.—When instructions were received to put the company in camp in Florida and prepare Fort Clinch for immediate defence, a spot was selected on an old sod covered with short Bermuda grass. By permission of the commanding general and the grace of the quartermaster, being close under the providence of an abandoned saw mill and pile of lumber, and the men generally artisans, handy with tools, we built boxes, with legs two feet high, on which the tents were placed. Thus we avoided disturbing the sod and had a charmingly wholesome and tidy camp.

The care of the health of men in camp means persistent, assiduous watchfulness on the part of their officers over personal habits of cleanliness; the location and general disposition of the camp; the cooking of food; selection of potable water; and last, though not least, over the moral influences likely to affect the nervous energy of men.

If Methodists want prayer meetings and a parson, or Catholics want mass and a priest; if some want songs and music and others want comedy and the stage, these requirements will be treated by the judicious officer as divine commands. They are both sources and stays of the health of men.

The philanthropic heart, moved by the enthusiasm of humanity which animated Jesus of Nazareth, finding itself in charge of assemblies of men, whether as officer, employer, or foreman, will recognize the responsibility as a divine commission. A man of this mould will know the recognition of the Master, who appreciates the care of his humblest creature as a devotion to himself.

IV. Barracks—Staten Island.—A mistake was made in building the shanty barracks on Staten Island too close to the ground; or rather, perhaps, in closing the space between the ground surface and the floor, and thus shutting off the breeze, which should have been availed of to carry off the exhalations from the earth under the houses.

The sheds were on a good but undrained sod. The floor, two feet above the ground, absorbed the damps arising from the earth below, thus fostering decay under the feet and lungs of men obliged to sleep and move in these confined quarters.

If the siding boards below the level of the floor had been omitted, the air drawing through and across the space would have kept the place dry and wholesome, and by furnishing a nourishing atmosphere to

the grass the vegetation would have consumed all miasmatic gases.

But as winter was approaching, a draught under the barracks would have made a cold floor. This was a real danger, but could have been avoided by laying a double floor, sandwiching a layer of tarred paper or roofing-felt.

A floor four feet above the ground gives excellent room for policing, as it exposes all untidiness and filth to general observation.

If it be absolutely essential to protect the space from the intrusion of small animals, it may be caged with two-inch battens; or, what is better, with wire in any desirable form. I think, however, it is better to leave it entirely open, since the sod under the house makes a nice loafing-place for the men in warm weather and in rain, being a change from the inside of the barracks and relieving the quarters for the time being from the exhalations of the men's bodies. The publicity of the place under such circumstances will be its protection.

Fort Clinch, Fernandina, Florida.—The boxed floors for tents in a Florida camp have been mentioned already. One important advantage in that case was the facility of moving the tents without striking camp. Once a week the men lifted their tents, moving them just their width, so that they were continually on clean, sweet earth, than which nothing, not living, is more lovely.

The barracks for the laborers in the neighborhood of the fort were another affair. There is no sod in that region. The grounds inside the fort were occupied by the garrison. It became necessary, therefore, to put the imported laborers and artisans in barracks on the beach outside the walls of the fortification, but near enough for their safety in case of need.

The common laborers among these men were uncommon wretches—the vilest scum of New York City slums; all foreign born and born as British subjects, who had come to a government work solely to escape draft in the military service of the country. Each fall they arrived duly impressed with the fact that, having a vote and being pets of the dominant party in the municipal government of New York, they controlled an important department of the nation and were thus entitled to control any government officer with whom they were pleased to engage their services. There was a terrible amount of loathsome disease among them, and their personal habits were abominably filthy. I weeded out the worst cases after a surgeon's examination, sending them back to their slums in the great city from which they had been poured upon me.

My first effort with these beings was to discipline them in the mess halls. When the noon bell rang they dropped every tool and rushed pell-mell for the dining-house, where, running along the table on which the food had been already spread, each man filled his hands with the boiled potatoes and then, seating himself, piled them around his plate, indifferent to the luck of the fellows who came after him in the race, and who might thus lose their share of the delicious fruit.

I confess it was a disgusting revelation of the character of a "superior race," who hung negroes to lamp-posts without benefit of clergy. What was to be done? I had two hundred and fifty of these brutes to care for.

First, I cut the long tables into sections, placed one end against a wall, and arranged for four seats on each side, or eight to a table. Hat pegs over the end of the table and a list of names posted on the wall told every man his place, and something of what he must do in the mess hall.

I cut a lot of barrels in two and, mounting them on

benches outside the dining-room door, had them filled with water for hand washing. The mess halls were not opened for the men to enter until every one of them had washed his hands. It was dreadfully and tyrannically cruel, but it brought us order and cleanliness. It was a blessing to the best men and a lesson to the others.

The sand flies of the Florida beaches are the pest of humanity in that region. In the quiet morning air, they rise in the eddy of calm along the houses and infest the entire habitation. If the house be raised to give the air free passage beneath it, the flies will be carried by and men may rest in comfort.

Our barracks were stilted up eight feet above the sand, giving men a shady place for rest when off duty and a wholesome, comfortable dormitory.

The negroes employed on the work, of whom there were always from two hundred to four hundred and fifty, slept with their families in the town, three miles from the work, but had their dinners at the fort. They possessed better natural manners than the class of white laborers sent from New York, or the white refugees from the mainland; were more cleanly, more industrious, and amenable to discipline. This comparison, however, does not make them model citizens or neighbors.

But the only deaths of laborers during those three and a half years were among the negroes who lived in the town of Fernandina. It may be properly said that they lived there and worked at the fort all the year round, while the imported laborers remained only from November to May, inclusive.

Chinese at Chimbote, Peru.—I have had some extremely interesting experience in the treatment of Chinese laborers in Peru. When I took charge of the Chimbote and Huaraz Railway, I found the men at the Port living in a galpon (barracks), with plenty of room but no supervising care. These people shut out every breath of air as if it had been pestilential, which indeed they believed it to be. The walls were covered with newspapers, and even the cracks in the floors were covered, to shut out the little breeze that might be felt by these sensitive organisms.

The galpon was so saturated with filth and permeated with stench as to be poison in every cubic inch of its structure. As a natural result, the doctor's daily call showed ten per cent. of the men continually suffering with fevers. The removal of the men being resolved on, they were put into a galpon which had been used at one time by a good class of mechanics of the work—a row of well-built, one-story rooms, fourteen feet square and twelve feet high. Putting three men in a room, each man, having built himself a neat, portable bunk, had nearly eight hundred cubic feet of space for life and use.

To make this more available by introducing some of the outside atmosphere, a row of two-inch auger holes was bored along the front facing the ocean, from which the breeze was constant, and just under the ceiling of the rooms. This was the more necessary because the men, determined to avoid the "exposure" thus forced on them, surrounded their bunks with curtains.

Once a week, on Sunday, they were made to empty their rooms of everything they contained and give their floors a thorough washing. After that, the manager and surgeon made a careful inspection of the quarters and, everything being in order the furnishings were returned to their places.

Within a fortnight fevers had disappeared so completely that rarely more than one in sixty of the men answered the doctor's call, and we had no serious cases.

Suchiman Plantation.—Thirty miles inland from the coast is the plantation of Suchiman. Here we had what may be called our stock farm; for here we

raised cattle for the work and our men, alfalfa, corn, and grain; and here we sent our sick, when no longer fit for duty in the shops or on the line.

We built a galpon at Suchiman (Fig. 1), which forced

FIG. 1.—The Suchiman Galpon. The drawing will be clearly understood in connection with the text describing it.

the men to breathe fresh air, whether they would or not. As at Chimbote, the wind is always from one direction. A slot six inches wide was made along the windward

side of the house, into which the air entered and was deflected upward along the under side of a table built against the wall, from which it projected three feet. On the front or inner edge of the table, a breast board extended upward six inches and downward to within six inches of the floor. Between this breast board and the table a slot one inch wide was left. The men's bunks were so arranged that the sleeper's head would be a foot below the top of the breast board and therefore out of the direct influence of the wind, while it would be in the region of an air continually renewed, giving the sleeper fresh air, while he felt no wind.

The effect was excellent; the sick recovered and only the American white man who had charge of them suffered, because he slept in a close house from which he shut out the "pizen night air" that he might enjoy the noisome exhalations of his own dirty carcass.

Summary.—I. Successful care of men in masses presupposes in the controlling authority something higher than doing duty simply because it is duty. The officer must have a benevolent regard for the comfort and happiness of the men who fall under his charge.

II. The first element of good health following the moral influences that protect the animal spirits and nervous energy of men is cleanliness—of person and quarters and surroundings; especially must care be given to the sinks, in which the deposits are to be continually covered with fresh earth. If deposits are made promiscuously in the neighborhood of the quarters, the men must be taught to cover them.

III. Fresh air for the dormitory is the next desideratum of health. It is one of the most important elements in its protection.

IV. The food demands constant and serious attention; first to protect it against the frauds of contractors and the carelessness of commissary agents—the must and fermentation of decay; and, second, to see it is properly prepared by the cooks to be wholesome diet for the men.

FIG. 2.—A Simple Distilling Apparatus. In the diagram, *A* represents a tin boiler, which may be set upon a stove or any other source of heat for making the water boil. *B* is a tin top or cover, in the side of which is a one-inch hole covered by a screw-top. A boiler of seventeen inches diameter will contain almost exactly a gallon for each inch of depth of water. The tunnel-shaped top of *B* runs into a sleeve at *C* and a descending tube of two inches diameter as here represented extends to the condensing plates *a, a, a, a, a*, and *b, b, b, b, b*, which are pressed-tin plates, twelve inches in diameter; the upper plates, *a, a, a, a, a*, are each one inch deep, while the under plates, *b, b, b, b, b*, are three inches deep. These plates should not be soldered together, as they must be left free for washing. The steam pressure is never sufficient to disturb them. On top of the upper plates, *a, a, a, a, a*, should be soldered a tin tube, three inches long and one inch in diameter; on the under sides of the lower plates, *b, b, b, b, b*, tubes two inches long, each of size to slide easily into the other. *E* is an earthen jar, standing on a low table, *P*, or it may be cased in ice. The pipe *D* may be of any length. When convenient it may with advantage pass out of the window, so as to allow exposure of the condensing plates to a lower temperature than that of the room, where a fire burns. A kerosene stove is a most convenient heating apparatus. Snow or ice or cold water may be put into the upper plate-hollows for expediting the condensing process, though it is not necessary, save for hurrying the condensation. The cool air of any climate will make this a convenient apparatus.

V. The most actively potent cause of disease among men changing location, is to be found in the drinking-water to which they are subjected. It may be entirely salubrious for the people of the district in which it exists, but to an interloper prove a radical danger.

It is the first matter to be investigated and cared for in establishing quarters. A distilling apparatus (Fig. 2) may be easily and cheaply made, but care must be observed in selecting the material of which it is constructed.

All the water drunk by the men, when it is not from distillation, must be boiled. The water of wells near towns, villages, the outhouses of farms and barnyards should be avoided as poisonous, until it has been boiled a good half-hour.

After boiling, the water should be bottled or in some other way protected from contact with the atmosphere.

It is even more essential that boiled water be filtered than if it were crude, since the putrefying remains of organic microscopic life are still to be eliminated.

But if water is drunk immediately after boiling, *i.e.*, before decomposition has set in, the organic matter digests harmlessly in the stomach, like any cooked food.

The filter should be an adjunct of every association of men. There are many excellent articles of the kind in the market, but every one may make his own filter, with the advantage of easily renewing it when no longer fit for use (Fig. 3).

The filter will remove matter in suspension; it will also clear the water of a large proportion of many salts.

Sand is the only proper material for a filter. Charcoal is a delusion. It is worse than nothing, for after the continuous use of a few hours it loses its capacity for purification and becomes foul, unfit for use.

The sand used in making a filter should be thoroughly washed of all earthy and clayey matter, until the water used in the process remains perfectly clear. After washing, the sand should be dried in an oven heated to 300 F., and remain exposed to this heat an hour. If, however, it is more convenient, the sand may be disinfected by boiling in clean water a half-hour.¹

Appendix—Note I.—The article mentioned in the text as "composition powder" is generally known and is sold by all druggists at the present day, being recognized as a convenient and useful remedy. It is composed as follows:

Bayberry bark.....	16 ounces, avoirdupois.
Ginger root.....	8 " "
Cloves.....	1 ounce "
Cinnamon.....	1 " "
Cayenne pepper.....	1 " "

To be ground and thoroughly mixed, and, for convenience in use and transportation, packed in two-ounce papers.

Note II.—In connection with composition powders, a liquid preparation is made by the same school and sold by druggists as "Number Six." It is a non-alcoholic stimulant, convenient for use in camp and in situations that demand quick treatment, when to wait for boiling water to make composition tea would be inexpedient.

"Number six" has been successfully used in sudden attacks of diphtheria, both as a gargle and stimulant, to protect the patient till a physician arrives to take charge of the case.

FIG. 3.—This filter is of the simplest and cheapest construction, easily put together by the least ingenious housekeeper. It consists of two flower pots and a common water jar, C, popularly known as a "monkey." Every piece should be of unglazed earthen ware, whereby the "sweating" may, by the process of evaporation from the outer surface, cool the contents. Put a sponge into the hole of the upper jar at A, and be careful to wash it daily, by boiling. A is a wooden cover. The filter in B is of fine sand, on a layer of fine gravel, under which is a layer of coarser gravel. In preparing the materials for the filter the disinfecting may be done conveniently by boiling the various components in a cotton bag.

FIG. 4.—A barrel cut out for a sitz bath. A few extra nails will be required in some of the hoops, notably those at the top of the barrel. They should be put in before the barrel is cut.

Note III.—In dysentery, especially when it has become chronic, my experience teaches me that drugs cannot cure. The only absolute remedy for this dreadful disease is ripe fruit. Watermelons in their season are to be reckoned the supreme remedy. Ripe peaches, plums, pears, and apples are excellent. Of all this class, the apple stands at the head as a curative agent. In using apples, which have the advantage of being at all seasons attainable when other fruits cannot be procured, it is well that care be taken to masticate the fruit thoroughly; or pulp may be scraped with the bowl of a spoon to insure perfect maceration. If, however, the apple is not perfectly digested, but is voided in crude particles in the stools, there is no occasion for alarm; a beneficial effect will be produced. The mucus which finally develops a pseudo-membrane will be torn from the walls of the intestines and their healthy action restored. The patient may expect one or more violent evacuations after beginning the use of fruit till the intestines have become cleansed. Then reaction will set in, with constant improvement of the condition.

In the tropics, physicians use this remedy for subjects as tender as infants with teething dysentery.

¹ The reader is referred to the appendix for the details of several matters treated of in the text.

Note IV.—The sitz bath of sea water, when attainable, is a great reinforcement of the fruit treatment in both chronic diarrhœa and dysentery. Everybody may have a sitz bath who can command a common wash tub or a half-barrel. A very comfortable sitz bath may be made with a pork barrel or any other that will hold water, as illustrated in Fig. 4.

Note V.—For convenient use in one's quarters, a bathing mat is readily made by having a rope (say half an inch in diameter) sewed into the edge of a piece of duck a yard and a half square. If the duck prove too light for the purpose, a coat of white lead paint will make it right. Standing on this, with a wash basin and sponge, the water will be held by the mat, and after the bath may be poured into the basin or pail for removal.

Note VI.—It is a great pity that the water-closet seat has not received serious attention from the hygienists. It has important influence in producing or preventing piles. As generally constructed by the stupid building carpenter, it is supposed to be a comfortable seat. It is rarely that, and when it is its purpose is only partially accomplished.

A properly constructed seat should open the body to assist nature in its desire for cleanliness. The common carpenter imagines it essential that the whole body be thrust nearly through the seat and I find it difficult to hold him down to a proper plan, which he always insists "is not large enough." The opening in a seat should give abundant room for the functions of the organs employed and no more. That accomplished, the rest of the seat should afford repose. Such a design will be found in Fig. 5, with directions for making. It will separate the features, protecting them from soil.

But, after all, there is no perfect cleanliness without free use of water after the stool.

FIG. 5.—Water Closet Seat. For making, inscribe an ellipse with axes of nine and five inches respectively, on the under side of the seat. Then, from the same centre describe a circle with a diameter of nine inches on the upper side of the seat. Saw out the ellipse. Then turn the board over and bevel it from the line of the circle down to the line of the ellipse. Use inch-and-a-quarter stuff.

Note VII.—The Bathroom and Water Closet.—These conveniences, viewed from the sanitarian's station, are among the most important apartments of the dwelling, but under the influence of a stupid economy and an arrogant ignorance are most often located in the very place which should be avoided.

It is difficult to understand why the average archi-

tect masses all these conveniences in a single room, unless it be that he is an ignoramus in respect of hygiene and the brutal laziness of servants.

The temptation to wash chamber vessels in the bathtub can hardly be resisted by the common maid of all work. She never uses the tub for her own person and thought of filth in its connection, therefore, never disturbs her. If it did the result would be the same.

It should be an absolute condition that, when there is sunshine, it be permitted to enter the bathroom to be on or near the person of the subject bathing. Generally in populated districts this may be accomplished by having the upper half only of the window made in clear glass. Sometimes it is better accomplished by using the ordinary glazing for the entire window and setting up a spring shade that rolls at the bottom instead of at the top. Thus, to screen the room, the shade may be unrolled from the bottom of the window and drawn up by a cord over a pulley as far as is necessary to secure privacy, leaving a space above for the admission of light and sunshine, when there is any.

The common plan of "tubbing" is an abomination, unless the water is a current flowing from the bottom of the tub. To put the whole body into a tub of standing water, in which all parts are washed at once, recommends itself as the filthy practice of the nice, unthinking multitude.

The ordinary shower bath is hardly bearable to many delicate subjects, and then there is objection to entering a small closet confined by India-rubber curtains, the arrangement in some public bathrooms.

Let the bathroom have a water-tight floor space at least six feet square, with a drain pipe from below and water-tight wainscoting around the walls. Then a pan at the ceiling, or an arrangement of pipes covering an area of four and a half feet square, should be pierced with extremely fine holes very close together. This arrangement will yield a gentle rain, not a sudden, severe downpour. The bather, no matter how delicate, may stand in this pleasant shower and enjoy a thoroughly delightful bath with the consciousness that whatever ought to leave him is being carried away. Such a bath is exhilarating, wholesome, and cleanly, which a tub bath in standing water cannot be.

Certainly money will provide various adjuncts to this arrangement, by which the luxury of the affair will be increased. But the present object is to show the man of modest means how to possess a luxury, without increasing the ordinary expense of his bath appointments, by substituting a clean bath for the nasty tub.

For purposes of sickness, the rain bath is most perfect and vastly more convenient in use than the tub, for a chair may be placed in the shower space and the temperature used that suits the demand of the attending physician.

The tub has no place in the best civilization.

The Water Closet should have the same advantage of light as the bathroom. It should be large enough to contain the seat, a sink for washing chamber vessels, and a sitz bowl or "bedell," and a wash-hand stand, with towel racks for the sink, bedell, and washstand. Repeating what I have said elsewhere, that there is no cleanliness after stools without the use of water, let the person be carefully treated on the sitz bowl, a neat arrangement by which a little spray of water is raised lightly against the body and then dried with the towel. This habit will correct the tendency to many local troubles, such as eczema, fistula, and piles, when they do not proceed from errors of diet.

Abundance of light in the water closet reinforces an important but rarely considered advantage of the

open basin containing water for receiving the evacuations of the bowels. It assists that constant watchfulness over the intestinal condition, so helpful in preserving the health, as a guide and caution in one's dietary habits. If, however, it leads to indulgence in drugs or physic, without the advice of the family physician, it were better to return to the hopper closet with all its horrors.

Progress of Medical Science.

The Theory of Hemisystole.—In opposition to Leyden and those who have maintained that the intermittent pulse was due to a pause in the action of the left ventricle, while the right ventricle continued to act, François-Francke, according to *The Practitioner*, argues from observation and experiment: 1. That mitral hemisystole—that is to say, the double pulsation of the right ventricle in opposition to one pulsation of the left ventricle—is to be found in mitral insufficiency neither in man nor in animals. 2. Intermittencies of the pulse in mitral insufficiency, as also in analogous arrhythmical disorders without mitral lesion, are due to aborted systole of the left ventricle. 3. That these aborted or abortive systoles may be shown to be synchronous in the two ventricles. 4. That there are no facts which can justify the discussion of a systolic reduplication situated in the right ventricle. 5. That it is not the supplementary systole of the right ventricle which produces the dilatation with hypertrophy of the left ventricle met with in mitral insufficiency. Sphygmograms which accompany the paper bear out the author's contention. He may be said to have flogged a moribund if not dead horse, but the work was not unnecessary and he has done it well.

Evisceration in Protracted Cross-Birth.—Dr. Mermann relates five cases in which he found evisceration sufficient to allow of speedy extraction when transverse presentation had rendered labor dangerously long. According to the *British Medical Journal* all recovered but the fifth patient, who died on the tenth day of pneumonia, attributed by her family doctor to some accidental chill not associated with delivery. The first patient was a primipara, aged twenty-nine. The membranes had ruptured five days before delivery; the child had been dead at least a day; turning could not be effected. After evisceration turning proved easy, and the exhausted patient recovered. The second case came under Mermann eighteen hours after the membranes had been ruptured by the midwife, who applied a tampon, as there was flooding. The right arm was prolapsed and œdematous; the shoulder impacted in the brim; the cord much prolapsed, swollen, and livid. The mother's abdomen was tympanitic. The uterine contractions were very painful, the temperature was over 100° F. After an attempt to turn, evisceration was performed and a large child extracted by pulling with the finger hooked into the thorax. The patient recovered after an attack of parametritis. In the third case the waters had escaped seven days before delivery and the child had been three days dead. Version had been attempted several times in vain. After evisceration the child was seized round the abdomen (as in Case I.), turned, and delivered with ease. In the fourth the shoulder of the dead child was firmly impacted in the contracted pelvic brim and the waters had slowly dribbled away. The scissors used for the funis served for evisceration; the child was then delivered by traction on the arm; recovery was rapid. In the fifth (noted above as a fatal case) both arms

were prolapsed and the left shoulder impacted. The waters had escaped three days before delivery. Attempts to turn had been made with the aid of chloroform. Evisceration was undertaken and the child extracted by pulling on the interior of the thorax. The patient did well till pneumonia set in.

Genu Recurvatum.—The Paris correspondent of the *Medical Press* explains that Dr. Campenon was struck with the frequency of *genu recurvatum* in coxalgia and in chronic disease of the hip in general, in the young subject. The deformity presents different degrees and the difference between the heel of the healthy member and that of the opposite, the patient lying on the back, varies from one to several inches, according to the nature of the case. Hyperextension of the leg, which characterizes the *genu recurvatum*, does not generally exist alone when the deformity is not of recent date, for with it is frequently remarked a certain mobility of the joint due to laxity of the lateral ligaments. There is also noticed a considerable atrophy of the muscles of the thigh. The deformity of the knee is mostly seen in very young subjects, under ten for instance, while over that age it is more rare. Long detention in bed is a very active predisposing cause, while the determining cause is mainly due to the position in which the limb is placed and kept. Consequently, the limb, instead of being forcibly extended, should be lightly flexed.

Unusual Variety of Hæmaturia in a Case of Vesical Tumor.—Dr. Ferria has recently observed the case of a patient aged twenty-four, who complained of painful micturition and hæmaturia. This latter symptom had been two years in existence, hemorrhage occurring at considerable intervals at first; latterly more often, with increased pain and frequent urgent desire to empty the bladder. The hemorrhage occurred more abundantly at the close of the act of micturition till shortly before advice was sought, when severe pain occurred at the beginning of the act and bleeding on almost every occasion, and only at the beginning also, the remaining urine being limpid. On examination it was determined that there was a considerable degree of retention, and that while the prostate and seminal vessels seemed normal, the sound, when introduced, on approaching the neck of the bladder came in contact with a surface apparently irregular and friable. On relieving the retention the catheter enabled Dr. Ferria to recognize a tumor in the bladder. Suprapubic cystotomy was performed and a papilloma found on the anterior bladder wall to the left side, about three finger breadths from the urethral orifice. The pedicle was slender, two and one-half centimetres in length, and the tumor was of the size of half a walnut, with a prolongation on one side which reached the neck of the bladder and penetrated the prostatic urethra.—*Annales des Maladies des Organes Génito-urinaires.*

Cancer and Toxins.—The treatment of cancer by toxins is not justifiable unless there is a marked benefit in a few weeks. Early and thorough excision is imperative.

Osteomyelitis.—Dr. Pinckney French, in *Memphis Medical Monthly*, February, 1896, in an article on early operation in osteomyelitis confidently urges as follows:

1. It affords opportunity for removing the local cause of the disease.
2. It relieves and prevents pain.
3. It prevents or limits necrosis.
4. It prevents septicæmia and pyæmia.
5. It prevents infection of adjacent soft structures.
6. It shortens the duration of the disease.
7. It expedites recovery.
8. It greatly diminishes the mortality of the disease.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, March 21, 1896.

THE INSANITY LAW AGAIN.

WE took occasion in our comments on "The Insanity Law," now before the legislature of this State, to suggest the reorganization of the lunacy commission on a basis commensurate with the fourfold increase of the insane now under its supervision and with the extraordinary powers and duties which the measure proposes to confer on that body. Our correspondence in the mean time proves that we voiced the opinion of the medical profession of the State, not only as to the necessity of a reconstruction of the commission, but as to the method of effecting that object. Our contention is that the present commission was created for an entirely different purpose than that contemplated by this bill. It originally had no executive powers or duties, but was required simply to visit and inspect institutions. For the proper performance of these duties, with the then number of insane in State care, this commission may have been competent. But now the insane in State institutions have increased from five thousand to nearly twenty thousand, and this bill invests the commission with enormous executive powers and duties, confers on it the control of a vast amount of patronage, and gives it unlimited discretion in the annual expenditure of the largest sum of public money at the disposal of any department.

That a commission should now be created competent to the proper discharge of these new duties and responsibilities is too evident to require further discussion. The method of reorganizing the commission which we proposed has met with general approval in our profession, and we commend it to the favorable consideration of our legislators. In formulating an amendment which will give effect to our views, we propose that there shall be a fixed representation of the medical profession in the commission. For this purpose we recommend that the commissioners from the Long Island, Manhattan, and Buffalo State Hospital districts shall be eminently qualified physicians. We select these districts to be represented by medical men because there will never be any difficulty in securing as commissioners physicians of the highest grade of qualification, and because the State hospitals located therein contain nearly one-half of the insane in State care. The lunacy commission, as thus constituted, would consist of three medical men representing the

great metropolitan State hospital districts and eight business men representing the other districts. Such a commission would at once command the confidence of the medical profession of the State and of the public generally.

A more careful study of the law reveals so many defects that it seems doubtful if it ever passed under the revision of a competent lawyer. For example, the salaries of the commissioners are to be fixed by the Governor, which violates that clause of the Constitution which requires that the salaries of all State officers shall be fixed by law. Again, this law admits of the change of a salary during the term of office, which the Constitution prohibits. These are but two of the many striking proofs of the looseness with which the law has been drawn.

THE INFLUENCE OF THE SPINAL NERVE FIBRES UPON THE GANGLIONIC CELLS.

WE have before us an excellent piece of scientific work in the form of an essay which gained the prize offered by the American Neurological Association, and which is entitled "The Biological or Morphological Constitution of Ganglionic Cells as Influenced by Section of the Spinal Nerve Roots and Spinal Nerves." The author is Dr. B. Onuf, of Brooklyn, and his work is so carefully and intelligently done, and offers such a model of how scientific research should be made, that we venture to present our readers with some analysis of its contents, although the subject is hardly to be called a practical one. Dr. Onuf calls attention to the fact that heretofore authorities have disagreed as to whether the motor cells of the spinal cord were affected by degeneration and atrophy when the motor nerves or nerve roots are cut off. He, therefore, sets out to determine by experimental evidence what is the actual truth in the matter. He was enabled to carry out his researches with more completeness by reason of the fact that within the last few years several new methods of staining nerve fibres have been discovered. By the method known as that of Marchi, for example, it is possible to find out whether nerve fibres are degenerating and to catch them, so to speak, *flagrante delicto*, since this stain does not affect healthy nerves nor does it affect a nerve that is entirely atrophied. By a new method of staining nerve cells devised by Nissl one is now able to discover the finer changes in the structure of nerve cells. Taking advantage of these two methods, Dr. Onuf made his experiments upon the dorsal nerves of cats, using these nerves in preference to those from the lumbar and cervical region, because their origin and distribution are simpler. The nerves were resected in some cases at a distance from the cord, in other cases at the roots. The animals were then killed at various periods, ranging from six days to several weeks after the operation. The results of the experiments showed that when the motor nerve roots were resected, there took place in the motor cells in the anterior horns peculiar degenerative changes, which were characterized by swelling and a homoge-

neous transformation of the cell contents, with a peculiar reaction to the dyes. This process was called "homogeneous degeneration." The change, if continued, ended in the liquefaction of the cells and their almost complete atrophy. When the nerve fibre was cut off at some distance from the cord, there took place in the anterior cells a simpler change, consisting of a gradual shrinkage, a sort of drying-up of the cell. This degenerative change was less severe and more easily recovered from than the other form. Both kinds of degeneration may be looked upon as curable conditions, such cure taking place upon the regeneration of the nerve root or the nerve fibre itself. There seems to be thus established a close nutritive relation between the nerve fibre and the cell from which it is projected, the health of the latter varying with that of the former. If, therefore, in cases of nerve injury the nerve is cut entirely across and does not unite, there will eventually occur a dry atrophy of the motor cells from which the nerve springs. But if the nerve grows again and its function is restored, the nerve cells develop again. It was also shown that retrogressive changes occur in the cells that are connected with the posterior roots, though the changes here were not, apparently, so minutely studied. By means of this method, Dr. Onuf also succeeded in localizing the function of certain groups of cells in the spinal cord, showing, for example, that the groups lying near the middle line, and known as the "mesial group," are related to the nerve which innervates the muscles of the back.

Some interesting information is given also in regard to the technical methods of staining nerve fibres and cells.

Altogether, the essay is very creditable to the author and to the judgment of the American Neurological Association.

CHOLERA IN CALCUTTA AND ANTI-CHOLERAIC INOCULATION.¹

WE have received these two deeply interesting reports through the kindness of Dr. W. I. Simpson, health officer of Calcutta. They cover the entire period from Dr. Haffkine's first inoculation in April, 1893, to the end of August, 1895. In judging the results of inoculation Dr. Haffkine speaks with great reserve and modesty of his grand work and his noble efforts to stay this dread disease.

Of the observations made, the doctor selects those in Calcutta, Gya, Lucknow, and the Kolacu Gardens as giving the best basis for judging the results of the inoculations.

In the Gya jail the inoculations made during an epidemic led to a gradual diminution of occurrences in the first ten days of application, a diminution which finally brought about a difference from twenty cases with ten deaths among the uninoculated to eight cases with five deaths among the inoculated—a reduction of two and a half to two times respectively.

¹ "Anti-Cholera Inoculation," Report to the Government of India, by W. M. Haffkine, M.D., Sci.D.

In the Kolacu Gardens the result of the inoculations was a reduction of cases and deaths in the proportion of one to four, the number of occurrences being four times less in the inoculated as compared with the uninoculated.

With reference to the results obtained from March, 1894, to July, 1895, in 19,473 individuals inoculated, Dr. Haffkine said: "They seem to indicate that in inoculation by this method we possess a means of effectively combating cholera epidemics." He goes on to say, moreover, that the process is still in the experimental stage, but the results "justify steps being taken to give the inoculations a more extended application."

It seems that the effect of the vaccines lasts but a limited time, and Dr. Haffkine says that of course the power of producing a lasting effect would increase the value of this inoculation very greatly. It is possible that such an effect can be obtained by a simple increase in the strength of the vaccines in the doses administered, but this again is a question which can be solved only by long years of observation.

The very guarded and modest statements as to the good results of his great work are evidently not shared by Dr. Simpson, the health officer of Calcutta, who speaks enthusiastically of Dr. Haffkine's labors. He says: "The most important event which has happened during the year in connection with cholera has been the introduction by the commissioner of Professor Haffkine's system of inoculation. It was introduced as a tentative measure for the period of one year, but the results have been so favorable that I trust that steps will now be taken to make the inoculation a permanent institution in Calcutta."

In speaking of an outbreak on March 25th in a certain section of Calcutta grouped about two tanks (the great source of cholera epidemics in India), Dr. Simpson says it "led to the inoculation of one hundred and sixteen persons in the bastee (district) out of about two hundred. Since the one hundred and sixteen were inoculated ten cases of cholera had appeared (up to the time of his writing, August, 1895) in the bastee.

All these ten cases occurred among the uninoculated portion of the inhabitants, and none of the inoculated were affected.

Furthermore, in summing up the final results of the inoculation in India, Dr. Simpson says: "It must, I think, be admitted that the evidence which is accumulating is gradually becoming so strong as to remove all doubts regarding the efficacy of the inoculation in rendering the body more resistant against cholera. As to the duration of the protection, time alone can settle."

Scruppox is a new disease to which football has given rise in England. It is a pustular eruption, coming indirectly from dirty jerseys and affecting especially the forwards in Rugby football, who have to shove in scrimmages. It has been proved to be contagious. Bacterioscopic examination has shown the presence of the staphylococcus pyogenes aureus.

NEO-VITALISM.

A TENDENCY in some quarters to return to the old "vitalistic" theory of living matter has been noticed. Professor Bunge gave the first serious impulse to this movement in a series of lectures delivered several years ago. In his presidential address before the American Microscopical Society last summer, Professor Simon H. Gage said: "It can be stated without fear of refutation that every physiological investigation shows with accumulating emphasis that the manifestations of living matter are not explicable with only the forces of dead matter." This announcement places Professor Gage among the neo-vitalists also. Sir William Thomson (Lord Kelvin) affirms essentially the same view. Professor Burdon-Sanderson evidently sees in this revival of a modified animism danger to scientific progress, and in a lecture recently delivered before the Royal Institution argues against it. The mystery of vital phenomena he prefers to call still a mystery. He denies that it is a new form of force, but rather an unexplained form of known forces, chemical or physical.

The neo-vitalists do not assert that the life force is something spiritual, a *deus ex machina*, as was formerly held. Their contention is that it is another form of force, having its chemical and physical equivalents.

We confess to a sympathy with the neo-vitalists, nor do we see any danger to continued serious investigation in supposing that there is a peculiar and unique phase of energy, a specific mode of etheric vibration perhaps, underlying the activities of living cells.

News of the Week.

More Rays of Light.—There seems to be no end of discoveries in connection with the recent announcement of the remarkable work of the now famous professor of Würzburg. The latest addition to our knowledge of what until recently seemed a field of darkness comes from Dr. Emmens of this city, who is known as an investigator and the inventor of a powerful explosive, "emmensite." There seems now to be a possibility of reflecting the "X" rays and so concentrating them that photographs instead of mere shadow pictures can be produced. Dr. Emmens is said to have obtained pictures of objects enclosed beneath the vulcanite screen exposed to sunlight for thirty-six hours. Certain outlines and shadows convince him that "X" rays are reflected. Pursuing his investigations and acting upon the theory and belief that "X" rays are universal, an attempt was made with apparent success to collect them from darkness by the aid of various chemical compounds. An instrument which he has invented and calls the photoscope will, it is thought, when completed, enable the surgeon to see with his own eye the interior of certain portions of the body. In this connection we again refer to Professor Salvioni's method for enabling us to see through solids as through a photographic camera. The appa-

ratus used consists, as previously described, of a cardboard tube, one end of which is closed by a sheet of black paper coated with a layer of fish glue and calcium sulphide or platinum cyanide, either of which compound is very phosphorescent under the action of the "X" rays. The other end of the tube contains a lens giving a clear image of the phosphorescent paper. The plan is to transform the Roentgen rays into ordinary luminous ones before they reach the eye. The paper is thus illuminated in those portions which receive the rays and the silhouettes of the objects appear dark. Professor Salvioni maintains that by the aid of a camera not only the shadows but the images of the objects can be reproduced, facts which appear to have been proven by Professors Battelli and Garbasso, of Pisa.

Diagnostic Features of Cutaneous Syphilis.—Before the section on general surgery of the College of Physicians of Philadelphia, Dr. George Henry Fox, of New York City, delivered on March 13th an address on "The Diagnostic Features of Cutaneous Syphilis," illustrated by a large number of lantern slides. Dr. Fox maintained that the cutaneous lesions of syphilis are characterized by appearances so distinctive as to be diagnostic to the experienced eye.

A Birthday Greeting to the Medical Record.—Dr. Thomas Osmond Summers, editor of the *St. Louis Clinique*, gives us the following sentiment on our thirtieth birthday:

"Of all the medical journals of America, whose name is legion, it is a conceded fact that the MEDICAL RECORD stands 'foremost on the files' of American independent journalism. There are many who 'assume this virtue though they have it not!' This cannot be said of the MEDICAL RECORD. Although we have ever felt sincerely the rupture which, like a manifest destiny, appeared unavoidable between the MEDICAL RECORD as the general representative of New York Medical 'cultus' and the American Medical Association, we have never, even in our close allegiance to the Association and the 'Old Glory' of American medicine—the code of ethics—ceased to recognize the spirit of progress, the wide sweep of journalistic power and influence, the lofty tone, and the leading trend of American medical thought that have made the MEDICAL RECORD the ringing keynote of American medicine. One thing is certain, however, whether professionally or commercially considered—the latter, of course, being the direct corollary of the former—the New York MEDICAL RECORD is the *deus ex machina* of American medicine—and 'there you have it.'"

[We tender thanks accordingly, and take fresh courage.—Ed.]

The Medical Record's Roentgen's Skiagraph.—It will interest our subscribers to know that the Roentgen picture in our issue of February 15th is on sale in at least one optician's window in this city, at one dollar per copy. It is probably one of the best that has yet been issued. We sent out nearly twenty-five thousand copies of the picture.

State Care Clothes Tax.—The lunacy commission persists in demanding that patients for asylums transferred from city institutions shall be supplied with new suits of clothes at the city's expense. This is another indication of the senseless autocracy of the lunacy commission in absurd details.

A Doctors' Car to the American Medical Association's Meeting in Atlanta.—To relieve any one who may desire to attend the meeting of the American Medical Association in Atlanta from as much care as possible, the publishers of the *MEDICAL RECORD* will on application furnish full information as to the route via rail, with cost of reduced round-trip tickets, etc. It is probable that a sufficient number will go from or through this city to secure an entire through "car for the doctors." There will be nothing lost by an early application for information.

Obituary Notes.—**DR. WILLIAM SAVERY** died at his home in Germantown Pa., on March 13th, at the age of sixty-three years. He was graduated from the Philadelphia College of Pharmacy in 1854, and was appointed resident apothecary and medical registrar in the Friends' Asylum for the Insane at Frankford, serving in that capacity until 1860. He was graduated from the medical department of the University of Pennsylvania in 1861, and was resident physician in the Wills Eye Hospital from 1861 to 1862, and in the Pennsylvania Hospital from 1862 to 1863. He was a volunteer surgeon in the United States Hospital at Fredericksburg, Va. In 1870-71 Dr. Savery was physician to the Winnebago tribe of Indians in Nebraska, and from 1872 to 1888 attending physician to the Hospital of the Good Shepherd near Bryn Mawr.—**DR. PHILIP R. PALM** died at Allentown, Pa., on March 6th, at the age of seventy-one years. He was a descendant of a long line of physicians, his great-grandfather having come to America in 1750, and was graduated from Jefferson Medical College in 1846. He was a member of the Pennsylvania Legislature in 1859, and was a voluntary assistant surgeon in the war of the Rebellion.

Free Antitoxin for the Poor.—At a recent meeting of the Philadelphia Board of Health a resolution was adopted providing for the free use of the diphtheria antitoxin prepared in the municipal laboratory and for the free practice of intubation among the indigent sick, always upon the request and with the co-operation of the attending physician.

The Leidy Fellowship.—The fund for the Leidy Fellowship of Anatomy has reached the encouraging sum of \$12,000, and it is hoped that the entire amount of \$30,000 will be realized before the close of the year.

Dr. S. Weir Mitchell, well known as investigator, practitioner, and writer, and designated by the University of Edinburgh last summer, in conferring its honorary degree of Doctor of Laws, as "the chief ornament to medical science in the New World," recently read his play, "Francis Drake," before the Garrick Club of the University of Pennsylvania.

A Chinese Physician in St. Louis.—Dr. Yung Mung Fueng, a graduate of the Royal Medical College of Canton, was recently registered as a practising physician in St. Louis, and has expressed his determination to open an office there.

A Worthy Example.—The physicians of London, Ontario, have entered into an agreement whereby one and all refuse to do contract lodge work any longer.

Tuberculin Denounced.—A cablegram from Berlin informs us that Koch's tuberculin has been warmly denounced in the Balneological Society. It is reported that Koch himself has by no means given up his investigations, and that he is about to publish a work advocating the further use of tuberculin.

Typhoid Antitoxin.—Dr. Chantemesse, of Paris, is the latest discoverer of a typhoid antitoxin. He has used the serum in three cases and claims that it had a rapidly curative effect, the patients passing quickly into the convalescent stage.

California State Society.—The twenty-sixth annual meeting of the Medical Society of the State of California will be held at Los Angeles, April 21st to 23d.

Sero-Therapy.—At a recent meeting of the St. Louis Medical Society the Subject of sero-therapy was discussed earnestly, seriously, and vivaciously during two meetings until long after midnight. The energy of giving and tolerance of receiving are exemplary virtues in our brethren of the city of professional love.

An Irate Female.—A female medical student who failed at a recent examination in London so effectually lost control of her inhibitory moral sense as to retaliate in the following ungrammatical convulsive outburst: "Very soon doctors will be drawn from we pure, noble-minded women, and you vile, drunken, filthy men expelled forever."

Longevity.—An interesting account of longevity in one family was recently published in the St. Thomas Hospital Reports. Mrs. B., born in 1630 (five years after the accession of Charles I.), died March 13, 1732. She was tended in her last illness by her great-granddaughter, Miss Jane C., born 1718, died 1807, and Miss Sarah C., born 1725, died 1811. A great-niece of one of these two ladies, Mrs. W., who remembers one of them, was born in 1803, and is at the present time alive and well. It will be seen from the above facts that there are three lives only to bridge over the long period between 1630 and 1896, and that there is at present living a lady who personally knew Miss C., who had nursed a relative born in 1630. The last lady of this remarkable trio is hale and hearty, and has just successfully undergone an operation for cataract.

Officers of a Medical College to be Arrested.—Warrants have been issued for the arrest of a number of persons connected with "Hering" Medical College, of Chicago, for the alleged illegal disposal of two bodies by putting them into a barrel and dumping the barrel into an alley.

A Wonderful Horse.—Dr. Paltauf, of Vienna, has a horse of which he is very proud. The causes of pride in horseflesh are usually the superb beauty of the animal, his record in the matter of speed, his ancestry, his temper, his style, his color, or his price. But none of these things have inspired the enthusiasm of the Vienna physician. His horse has beaten the record simply in the production of antitoxin units. The animal is a six-year-old gelding and the strength of his serum is five hundred antitoxin units. In the last year this noble animal has produced six quarts of toxin, and, while others have saved their hundreds, this horse has saved its thousands of lives. In the civilization of the future, and perhaps in the annual New York horse show of the future, the element of antitoxin may yet be taken into consideration in testing the qualities of the horse. We should respectfully submit to those gentlemen who run future horse shows that a collection of animals labelled with their toxin-bearing capacity would form a most interesting addition to the parade of fair women which is put on view on this occasion.

The First Hearing on Vivisection before the judiciary committee of the Massachusetts legislature was held recently and, according to the *Boston Medical and Surgical Journal*, the advocates of the measure did not make out a very strong case. No serious proof was offered of cruelty to animals in the physiological laboratories of Massachusetts or elsewhere, and one witness for the bill asserted that all those whose testimony did not agree with his were "liars."

The American Medical Publishers' Association will hold its third annual meeting in Atlanta, Ga., on May 4th. The secretary is Dr. C. W. Fassett, of St. Joseph, Mo.

The Tri-State Medical Society will hold its annual meeting in Chicago on April 7, 8, and 9, 1896. A long list of interesting titles of papers to be read has been published.

The Cornell Brain Association is an organization for mutual autopsy. It is said that this association has already received eight brains and has the promise of twenty-five others.

Municipal Appointments in Baltimore.—Baltimore has recently had a number of medical appointments under the new political régime and the mayor has named two homœopathic physicians to attend upon the inmates of the jail. These appointments have aroused a good deal of indignation among members of the regular profession in the city.

New Buildings for the City's Medical Charities.—The Commissioners of Charity have decided to build a new morgue, as the present one is entirely inadequate in its facilities. It is proposed to place it on an iron pier extending two hundred feet into the East River from the foot of Twenty-Sixth Street. The commissioners also contemplate the remodelling and extension of the almshouse buildings on Blackwell's Island and the erection of a new reception hospital at Fordham, in the annexed district of the city. The

cost of the proposed improvements will be about \$1,200,000, and it is expected that the legislature will grant an appropriation for the purpose.—*Boston Medical and Surgical Journal*.

The Phonendoscope.—This instrument is claimed by its inventors, Bazzi and Bianchi, to render perceptible all the normal and morbid sounds in the body far more distinctly than the ordinary stethoscope. It renders audible the sounds made by the foetus, by the circulation, by the muscles, etc., and also locates displaced organs by the noises made by their contents. It resembles a watch in appearance, and the two ear tubes can be multiplied indefinitely, so that several can listen at the same time. In auscultating a large surface one disc is simply placed upon it and the tubes are placed in the operator's ears. A tube is inserted into this disc when it is desired to circumscribe the auscultation. The contour of an organ can be accurately determined by the sound made by its contents through the tube as the operator lightly manipulates it with his fingers.—*Journal de Médecine de Paris*.

Elsner's Ready Method of Recognizing the Typhoid Bacillus.—In the *Zeitschrift für Hygiene*, Bd. xxi., 1895, p. 25, Elsner describes this method, to which reference has already been made in these columns: Ordinary gelatin is cooked with an infusion of potato (500 grams to the litre of water), and to this is added enough normal sodium solution to give a slight acid reaction, according to the method of Holz. It is then filtered and sterilized. When it is to be used, one per cent. of iodide of potassium is added, the mixture being then inoculated and plates made. Elsner has examined by the aid of this medium surface water, soil, etc., and when colon bacilli were present they grew with almost entire exclusion of other bacteria. The proteus and root bacillus, which he found grew readily on media containing carbolic acid, only occasionally grew at all on the new culture medium, and then were placed in the background by the colon bacilli. The colonies of colon bacilli show the characteristics which are present when they grow on any acid medium. The typhoid bacillus grows characteristically, so as to be readily distinguished from the colon. On the iodide-of-potassium-potato-gelatin, in twenty-four hours the typhoid-bacillus colonies are almost invisible under a moderate magnifying power, while the colon-bacillus colonies appear well grown out; in forty-eight hours the typhoid colonies appear as small, clear, shining, drop-like, finely granular growths, while the colonies of the colon bacillus are large, much more coarsely granular, and brownish. He has tested thirty different cultures of colon and typhoid bacilli, as isolated upon this culture material, by Pfeiffer's method (*i.e.*, the use of the specific property of the blood serum from typhoid-immunized animals), and in every case the identification was shown to be correct. In one instance a bacillus which was not distinguishable from the typhoid bacillus by ordinary culture methods was found, upon the use of the iodide-of-potassium-potato-gelatin plates, and also by Pfeiffer's method, to be a variety of colon bacillus. The typhoid bacilli

could be readily detected, even if very few in numbers. By the use of this method, typhoid bacilli were isolated from the evacuations of fifteen out of seventeen cases of typhoid fever; of the two other cases, one was in the seventh week, and defervescence had taken place in the second.

The Southern Empire State Medical Association of Georgia is an association composed entirely of colored regular physicians. The association is now entering upon its fourth year. Its three meetings have been well attended. The first meeting was held in Augusta, the second in Macon, and the third in Atlanta. At the last meeting the following papers were read and discussed: "The Uses of Mercury and Iodide of Potash in Syphilis," by Dr. Richard Cary, Griffin; "The Progress of Medical Science," by Dr. C. J. Cain, Rome; "Pneumonia," by Dr. G. P. Washington, Waycross; "Typhoid Fever," by Dr. E. H. Moyer, Columbus; "Care of the Teeth," by Dr. J. R. Porter, Atlanta; "Sickness and Injury Feigned," by Dr. H. R. Butler, A.M., Atlanta; "Blood Poisoning," by Dr. A. O. Lockhart, Atlanta; "Practical Therapeutics," by Dr. T. H. Slater, A.M., Atlanta. The officers of the association are as follows: Dr. E. E. Greene, *President*, Macon; Dr. C. S. Swan, *First Vice-President*; Dr. G. P. Washington, *Second Vice-President*, Waycross; Dr. J. E. Asbury, *Treasurer*, Atlanta, and Dr. T. H. Slater, *Secretary*, Atlanta.

Pleasant Laxatives.—Starting with the proposition, "Woman, thy Name is Constipation," Dr. Ben H. Brodnax, in the *Cincinnati Medical Journal*, contributes some notes upon his experience in the relief of the condition which he so thoroughly identifies with the gentler sex. Cascara sagrada is a good remedy, he says, but bitter, and he is not satisfied with the extract in pill form. He cordially recommends chionia, on the ground that it is pleasant to take and creates no habit. A preparation of castor oil and saccharin is, he says, very much more popular with children and himself than the original oil. Dr. Brodnax is very enthusiastic over a certain cathartic vegetable pill of somewhat the same composition as the compound cathartic pill and he also likes the phosphate of soda, which is now put up in a palatable form and sold under a trade name.

The Whale Cure for Rheumatism.—It is reported that at the town of Eden, a place in Australia which stands on the shores of Twofold Bay, there is a hotel where rheumatic patients congregate. Whenever a whale has been taken the patients are rowed over to the works in which the animal is cut up, the whalers dig a narrow grave in the body, and in this the patient lies for two hours as in a Turkish bath, the decomposing blubber of the whale closing around his body and acting as a huge poultice. This is known as the "whale cure for rheumatism."

Orificial Surgery in Germany.—The *Centralblatt für innere Medizin* thus scarifies that absurd reflex "philosophy" which has found expression in "orificial surgery": How a cough is cured in Kansas may be of interest to all, even if the cure be not imitated.

The writer of the paper, while passing his vacation at Manitou, the Mecca of America, was consulted by a vigorous, blue-eyed, light-haired Swedish girl of twenty-six summers on account of a cough and various nervous disturbances. The cure was as follows: First, the lady must reside in the same house with the physician. Then came phosphate of iron, chloride of potash, galvanization of the body, faradization and dilatation of the rectum (*North West Lancet*). Then followed galvanization of the solar plexus and of both vagi, nasal sprays, verbascum oil in the ears, and finally excision of the hymen and further dilatations and faradizations as already described, together with regulation of the diet and inhalations of oxygen, and the cure burst in upon this treatment like an avalanche in the mountains of the moon or an earthquake in the Sierra Nevada. A poem by an unnamed writer closes this medical history.—*Medical Standard*.

The Third International Congress of Dermatology will be held in London August 4 to 8, 1896. The subjects proposed for discussion and the names of those who will take part in them are as follows: "Prurigo."—Drs. Besnier, Paris; J. C. White, Boston; Kaposi, Vienna; and Payne, London. "The Etiology and Varieties of Keratosis."—Drs. Unna, Hamburg; V. Mibelli, Parma; H. G. Brooke, Manchester; and W. Dubreuilh, Bordeaux. "Syphilitic Re-Infection."—Drs. Fournier, Paris; Alfred Cooper, London; Lang, Vienna; and Fitzgibbon, Dublin. "The Connection of Tuberculosis with Diseases of the Skin other than Lupus Vulgaris."—Drs. J. Nevins Hyde, Chicago; Radcliffe Crocker, London; Hallopeau, Paris; and G. Riehl, Vienna. "The Duration of the Period of Contagion of Syphilis."—Drs. Hutchinson, London; Lassar, Berlin; Campana, Rome; and Feulard, Paris. "Ringworm and the Tricophytons."—Drs. Sabouraud, Paris; Rosenbach, Göttingen; and Malcolm Morris, London. "The Nature and Relations of the Erythema Multiforme Group."—Drs. de Amicis, Naples; P. A. Morrow, New York; T. H. Veiel, Stuttgart; and Stephen Mackenzie, London. "Malignant Syphilis."—Drs. Handlung, Copenhagen; Tarnovsky, St. Petersburg; and Neisser, Breslau. The congress has secured for its use the building known as Examination Hall, on the Victoria Embankment. This will afford every facility for all kinds of demonstrations—cases, pictures, museum, etc. It is urged that those intending to join the congress should notify the secretary, Dr. J. J. Pringle, 23 Lower Seymour Street, London, W., of their intention as soon as possible. The membership fee is \$5, which should be sent in the form of a pound-sterling draft on London, or P. O. order to the same amount.

Army Surgeons in Cuba.—Twenty surgeons of the Spanish army in Cuba have died during the year that the insurrection has been in progress. Of this number only three died from bullet wounds, the remaining seventeen of disease, in fifteen cases the disease being yellow fever. This is not a high mortality rate when it is learned that members of the medical corps in Cuba number more than three hundred.

Reviews and Notices.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In Twenty Volumes. Volume VI. Diseases of the Respiratory Organs. New York: William Wood & Co. 1896.

THE successive volumes of this encyclopædia appear at intervals of three months with a regularity that is as pleasing as it is unusual in works of the kind. The present volume, which is number six of the series, is really the fifth in order of publication, Volume V. being promised as the next to appear. This one deals with the diseases of the respiratory organs from the nose to the lungs. The first article, on "Diseases of the Nose," is by Dr. Prosser James, of London, a writer who needs no introduction to those who are familiar with the literature of affections of the upper respiratory passages. After an introductory section on rhinoscopy and general nasal therapeutics, the various affections of the nose, both external and internal, are dealt with in order and most satisfactorily. Dr. James' style is that of an experienced writer, and when to this is added a wide and matured knowledge of the subject we have a treatise that will commend itself to all who seek for an authoritative guide to the diseases of this organ. Next in order comes a contribution on the "Affections of the Accessory Sinuses of the Nose," by Dr. Jonathan Wright, of Brooklyn, whose original investigations have done much to throw light upon this hitherto obscure subject. The value of the article is much enhanced by some excellent illustrations showing the anatomical relations of the parts, and how a discharge from the frontal sinus may drain into the antrum without appearing at all in the nasal cavity.

Dr. E. J. Moure, of Bordeaux, justifies his reputation as one of the foremost of French laryngologists by a most comprehensive and perspicuous monograph on the "Diseases of the Nasopharynx and Pharynx." The same author treats in an equally satisfactory manner of the "Diseases of the Tonsils." The only illustrations of this article are of acute ulcerative lacunar tonsillitis, an affection which the writer has observed several times and which is ordinarily confounded with tertiary syphilitic ulceration, although entirely distinct from it. The possessors of this work are to be congratulated upon having these two treatises from such a master hand.

Dr. Albert H. Buck, of New York, contributes a short but thoroughly practical article on "Diseases of the Ear." The author has purposely avoided a disquisition on all the various and unusual ailments of this organ which could be of use only to the specialist, and has wisely utilized the necessarily somewhat limited space at his disposal by a presentation of what concerns especially the general practitioner. After an introductory section on the classification of aural affections, the author takes up in order the diseases of the external auditory canal, those which involve the middle ear, the methods of examination of the middle ear, and the diseases of the labyrinth and auditory nerve, the article closing with a discussion of the general principles of aural therapeutics.

The next article is on "Diseases of the Larynx," by Dr. F. H. Bosworth, of New York, whose name is a guarantee that the subject is well handled. The author does not think much of the larynx as a self-suffering organ, most of its catarrhal diseases being traced to similar and pre-existing affections of the nose and nasopharynx; consequently their treatment is principally that of the parts above. The author's therapeutic creed was indeed foreshadowed by the formula of the Connecticut Sunday-school teacher, whose advice to his pupils was always: "Be a good boy and keep your nose clean." The illustrations of this article are numerous and helpful. Considerable space is devoted to a consideration of the neuroses of the larynx, and the section on laryngoscopy is especially satisfactory.

"Diseases of the Trachea and Bronchial Tubes" are treated by Sir T. Grainger Stewart and Dr. George A. Gibson, of Edinburgh. The introductory sections are devoted to a consideration of the anatomy, physiology, pathology, symptomatology, and therapeutics of these affections, and then the individual affections of the trachea and bronchia are taken up seriatim. The treatment of these diseases receives special attention, many formulæ which the authors have found particularly beneficial being given. The section on bronchiectasis is an elaborate treatise on this affection and is

the best presentation of the subject that it has been our fortune to read. The closing article of this volume is on "Diseases of the Lungs," from the pen of Dr. Winslow Anderson, of San Francisco. It includes a consideration of all the affections of these organs except croupous pneumonia and tuberculosis. It is easily seen by the way the author handles his subject that it is one with which he is perfectly familiar, and he also possesses the happy faculty of imparting this knowledge to others in a most satisfactory manner.

The book, like its predecessors in the series, is well bound and clearly printed on good paper; the subjects treated of are among the most important in medicine; the authors are masters of their themes; and altogether the volume is one of the most instructive of any that have yet appeared.

AN ESSAY ON MALARIA AND ITS CONSEQUENCES. By ROBERT LINDSAY, A.M., M.B., F.R.C.S. Eng. London: H. K. Lewis, Gower Street. 1895.

THIS little book, comprising about one hundred pages, gives an interesting description of what the author believes malaria to be, laying great stress on the activity of carbonic-acid gas as a causative factor.

The interesting fact that micro-organisms and infection are active elements is completely ignored. The treatment is given in the author's own way, according to his experience, which appears to be quite extensive.

A MANUAL OF THE PRACTICE OF MEDICINE. By GEORGE ROE LOCKWOOD, M.D. Philadelphia: N. B. Saunders. 1896.

THIS manual, comprising over nine hundred pages, is composed of ten chapters. The author follows the classification of Osler almost throughout. There has evidently been considerable labor expended in bringing this book to completion, and although nothing really new is presented it is eminently practical. It is written in a very clear style and is profusely illustrated.

The book has been written to date, for in discussing the infectious diseases antiseptic treatments, besides bacteriological diagnosis, are carefully detailed. In discussing diphtheria the author gives everybody the benefit of doubts, for he mentions and illustrates calomel fumigation, which we think is a thing of the past. He also gives the formula of Loeffler's local treatment, but finally gives antitoxin ample justice, quoting by an illustrated chart the temperature, pulse, etc., of a typical case of diphtheria treated by Dr. L. Fischer.

Other illustrations showing the author's observation of Charcot's knee are exceedingly valuable. The author deserves credit for his first attempt and we hope his book will be well received.

THERAPEUTICS OF INFANCY AND CHILDHOOD. By A. JACOBI, M.D., Clinical Professor of the Diseases of Children in the College of Physicians and Surgeons (Columbia University), New York. Philadelphia: J. B. Lippincott Company. 1896.

THE author is so well recognized as the leading exponent of pædiatrics in our country that no doubt his views concerning therapeutics in children will be carefully perused.

I. Feeding of sick children. In the opening Jacobi gives general rules for the feeding of infants and lays stress on the necessity for giving (a) water, (b) cane sugar—not milk sugar, (c) common salt. He elaborates on this theme, but points also to the efficiency of water as a drink for healthy and for sick children, noting besides that water is indicated to aid in liquefying viscid expectoration in bronchitis and laryngitis; and its value in anæmia and fevers, when a deficiency of pepsin and HCl exists, to stimulate secretion of gastric juice.

Jacobi has found that cane sugar given to children for constipation will benefit them, especially if given with oat meal water. The author finds that when breast milk behaves like cow's milk in regard to solid curdling and consequent indigestibility, salt must be given.

II. Treatment of the newly born. Commencing with detailed management of asphyxia, including other methods besides the author's, he deals with atelectasis pulmonum, cephalæmatoma, hamatoma of the sterno-cleido-mastoid muscle, and sclerema. The article on bathing is a most valuable contribution to medical literature. He treats also of the mammae, mastitis, perimastitis, angioma, the care of the cord, omphalitis, umbilical gangrene, arteritis and phlebitis, umbilical hemorrhage, icterus, melana, trismus and tetanus.

We next come to blennorrhœa, umbilical fungus, hernia, and congenital constipation. Each subject is carefully detailed and valuable hints are given where required.

III. General therapeutics. Under this head Jacobi tells when and how to give an enema to children, detailing anatomical peculiarities. He tells how to prescribe and how to apply drugs by inunction; rectal medication and subcutaneous medication, the author believes, ought to be made more frequently than is customary. The chapter on inhalation is very instructive, particular attention being given to anæsthetics in tracheotomy. Jacobi, in discussing gargles, doubts their efficacy; preference is expressed for sprays or an insufflation of powder. Sinapisms, vesicatories, and depletions are minutely discussed.

IV. This chapter is highly interesting and deals with just such questions as are propounded daily. On page 93, for example, Jacobi elaborates the uselessness of continued nursing after ten months if no teeth appear, and gives dietetic directions for this condition.

In speaking of rhachitis, Jacobi mentions the fact that many cases should be prevented by attending to the parents before conception. He makes a new point by insisting on looking after the ears, for he believes that the slightest internal or external otitis is liable to produce convulsions. He then gives modern views on scrofulosis and therapeutic hints in tuberculosis. His next chapter deals with syphilis. This is truly a masterly article, for although the author condenses it into about five pages nothing has been omitted. The hemorrhagic diathesis and diabetes are discussed.

V. In this the author describes intermittent and typhoid fever, cholera, dysentery, scarlatina, measles, röteln, mumps, variola, varicella, erysipelas, diphtheria, rheumatism, pertussis.

VI. Diseases of the digestive organs.

VII. Diseases of the genito-urinary organs.

VIII. Diseases of the respiratory organs.

IX. Diseases of the organs of circulation.

X. Diseases of the nervous system.

In the last chapter are closely condensed such points as are necessary for such puzzling questions as are submitted to the average physician.

Jacobi clearly defines the uselessness of operations for the relief of idiocy. He details the method employed by Quincke of tapping the spinal canal at about the third lumbar vertebra, but adds that it never cures and merely aids in the diagnosis by proving the presence of bacilli in the cerebro-spinal liquor. Jacobi's book ends with a brilliant addendum in which all modern practical points are carefully brought out. His article on antitoxin shows that the author has carefully studied its application in diphtheria and readily indorses it. The painstaking labor of Dr. L. Fischer in bringing the new treatment into general use is not given its proper credit. Sterilization is thoroughly discussed.

Indeed, summing up, it is by far the best work on infant therapeutics in print to-day and, being up to date, is a valuable addition to the library and will be most readily consulted when the physician is baffled.

SPECTACLES AND EYEGLASSES, THEIR FORMS, MOUNTINGS, AND SPECIAL ADJUSTMENTS. By R. J. PHILLIPS, M.D., Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic and College for Graduates in Medicine; Ophthalmic Surgeon to the Presbyterian Hospital in Philadelphia, etc. Philadelphia: Published by P. Blakiston, Son & Co. 1895.

THIS little work now appears in the form of a revised second edition of one hundred and one pages. It is of convenient size and is excellently printed. The book is issued as an aid to those who prescribe and who sell eyeglasses and spectacles, for the purpose of enabling them to reach the most satisfactory and beneficial results in the adjustment of lenses to the eyes of patients. Since the proper adjustment of spectacles and eyeglasses is of very great importance, it is desirable that the rules and suggestions contained in this little volume should be familiar to every oculist and optician. The book before us presents the subject in a concise and fairly complete form. The first chapter describes the materials employed in the manufacture of lenses and frames, the forms of lenses, equivalents of lenses by different nomenclatures, etc. The second chapter deals with the centering and decentering of lenses, the proper relation of lenses to the eye, etc., and is an excellent exposition of this part of the subject. Chapter third describes the various measure-

ments required for the proper fitting of frames, and chapter fourth enters into the consideration of the inspection and adjustment of spectacles and eyeglasses. The remarks on prisms contained in this chapter are worthy of perusal. The work is sufficiently illustrated to promote a clear understanding of the ideas that the author has endeavored to present.

AN ATLAS OF OPHTHALMOSCOPY, WITH AN INTRODUCTION TO THE USE OF THE OPHTHALMOSCOPE. By O. HAAB, M.D., Professor of Ophthalmology, University of Zurich. Translated and Edited by ERNEST CLARKE, M.D., B.S. Lond., Fellow of the Royal College of Surgeons, Surgeon to the Central London Ophthalmic Hospital, Ophthalmic Surgeon to the Miller Hospital, etc. New York: William Wood & Co. 1895.

THIS admirable work consists of an octavo volume of fifty-five pages of text and sixty-four plates with the description of each plate placed opposite to it. The whole forms a small convenient volume, and is a happy contrast to the large cumbersome atlases that we are familiar with. The text, which is included in the work in the form of an introduction, gives a concise description of the principles of ophthalmoscopy and of the methods employed, without including perplexing formulæ. The simple language of the introduction will appeal to the student and general practitioner as well as to the specialist in ophthalmology, and give the work a much wider field of usefulness.

The plates represent the normal and pathological fundi of the eye, as seen by means of the ophthalmoscope, in chromo-lithography. The drawings are original. They were sketched from the image obtained by means of the indirect method and the details supplied by the direct method. The physiological and pathological conditions depicted are ninety-eight in number; they are excellently chosen as representative of the various conditions met with, and the work is beautifully and truthfully executed.

The interposition of the descriptions of the plates between the plates in their order adds much to the value of the work, as immediate information may be obtained without referring to other parts of the volume.

The present work forms one of a series of atlases to be published by Wm. Wood & Co.

The publishers are to be congratulated on the beauty and value of the first volume of the series.

LES SUPPURATIONS DE L'APOPHYSE MASTOÏDE ET LEUR TRAITEMENT. Par A. BROCA et F. LABET-BARBON. Mémoire Couronné par l'Académie de Médecine (Prix Meynot, 1894). Paris. 1895.

THE work presents an able review of a subject which has called forth probably more discussion than any other in the otological world. The advisability of opening the mastoid process in cases of acute and chronic purulency of the middle ear is strongly set forth by the authors, but we shall not attempt a discussion here of the advantages or disadvantages of such surgical procedures. The symptoms of involvement of the mastoid region are ably discussed and should aid considerably in cases of difficult differential diagnosis. The latter has always been more or less of a *bête noire* among otologists, and any help in the right direction should be made welcome. Space will not permit us to go more deeply into the subject under consideration; we can truly state, however, that it has given us much pleasure and satisfaction to read this book, and we heartily recommend it to otologists for careful study.

HISTORY OF ANÆSTHESIA OR PAINLESS SURGERY. By WILLIAM R. HAYDEN, M.D. (Pamphlet.)

CHARLES LAMB regretted that Charles I. did not hang Milton. We do not quote this *à propos* of any given person, but why will people return to such a perennial subject as the discovery of anæsthesia by ether? Dr. W. R. Hayden rushes once more into the breach for Morton. He calls a good many people rather hard names and proves to himself, at least, that it was Morton to whom we owe this discovery. The doctor makes a great to-do over the statue in the Boston public garden which Dr. Holmes said should be inscribed to "E(i)ther." Our own impression is that, if ei-ther Dr. Morton or Dr. Wells could return to earth and see this same monument, he would indignantly deny the soft impeachment.

A HANDBOOK OF OBSTETRIC NURSING, FOR NURSES, STUDENTS, AND MOTHERS. By ANNA M. FULLERTON, M.D. Fourth Revised Edition, Illustrated. Philadelphia: P. Blakiston, Son & Co. 1895.

THIS little book consists of practical hints for mothers, nurses, and physicians. While almost all points necessary for the accouchement have been detailed, such points as treatment of asphyxia have not been overlooked. It is well adapted for beginners, and as antisepsis forms part of this little book it is well adapted to give points to those not familiar with this subject.

THE RETROSPECT OF MEDICINE: A Half-Yearly Journal Containing a Retrospective View of Every Discovery and Practical Improvement in the Medical Sciences. Edited by JAMES BRAITHWAITE, M.D. Lond., Obstetric Physician and Surgeon to the Leeds General Infirmary, etc. Assisted by E. F. TREVELYAN, M.D. Lond., B.Sc., M.R., C.P., Assistant Physician to the Leeds General Infirmary, etc. Vol. CXII., July-December. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited. 1895.

THE *Retrospect* now looks back over fifty-six years of existence and claims our respect accordingly. The present issue contains a short *résumé* of nearly every important advance made in medicine, surgery, and obstetrics during the past six months. Although the arrangement under the subheadings is alphabetic, there is a good synopsis of contents and a full index.

DENTAL MATERIA MEDICA AND THERAPEUTICS. By JAMES STOCKEN, L.D.S. Eng., Pereira Prizeman for Materia Medica, Late Dental Surgeon to the National Dental Hospital. Fourth Edition. Revised by LESLIE M. STOCKEN, L.R.C.P., M.R.C.S., L.D.S., and J. O. BUTCHER, L.D.S. Eng., Assistant Dental Surgeon to Guy's Hospital. New York: J. H. Vail & Co.

In one hundred and fifty pages this small volume gives all the essentials of practical therapeutics as it is apt to interest the dentist. New remedies which have proven of practical worth to the dental surgeon have been added, as well as an index of diseases, and many portions have been rewritten.

THE JOHNS HOPKINS HOSPITAL REPORTS. Vol. V. 1895.

THERE is, perhaps, at this late day, no necessity for us to emphasize the great scientific and practical value of anything coming from those attached to this great hospital, and the report before us is no exception.

We regret that want of space will not allow us to do more than call attention to the elaborate and valuable study of "The Malarial Fevers of Baltimore," by Drs. William Sydney Thayer and John Hewetson; and to "A Study of Some Fatal Cases of Malaria," by Dr. L. F. Barker, Assistant Resident Pathologist. The plates illustrating the parasite of tertian, quartan, and æstivo-autumnal fevers are exceptionally beautiful; we notice, by the way, that they were done in Leipzig.

The remainder of the report is taken up with "Studies in Typhoid Fever," by Professor Osler and his assistants. Of these the most important is by Osler himself, entitled "Five Years' Experience with the Cold-Bath Treatment in Typhoid Fever." Osler to our thinking is the most learned and scientific clinician on this side of the water, and an expression of opinion from him upon such an important point in the treatment of this disease merits more than casual comment.

Professor Osler says that "for the past five years, ending May 15, 1895, systematic hydrotherapy has been used, the method of Brand, with certain minor modifications"; to wit, a tub bath of twenty minutes at 70° F. every third hour when the rectal temperature is at or above 102.5° F.

Frictions were applied in the bath and a warm drink or a stimulant was given afterward. In a large majority of cases no other treatment was employed. If the pulse was feeble whiskey was given and strychnine. The diet was either wholly milk or in part broths and egg albumen.

In connection with the method of compiling those troublesome and often delusive things called "statistics," he makes the important point that in estimating the value of any treatment all circumstances should be taken into account, and he has dealt with the statistics as so many patients admitted, of whom so many died; and he goes on to say that "this should be done in all institutions. Give the total num-

ber of cases of each disease treated to a conclusion and the number of dates, irrespective altogether of the length of stay in the hospital or the condition on admission."

After reviewing the various cases or groups of cases treated the author says: "Two advantages are claimed for hydrotherapy in typhoid fever: a mitigation of the general symptoms of the disease, and a reduction in the mortality. Our experience during the past five years bears out these claims."

As to the first of these, Osler thinks it is a mistake to claim that severe nervous symptoms are never seen. In the first three years there were thirteen and in the last two years nine cases of delirium.

As to the reduction of mortality, the author states that the average mortality in general and special hospitals throughout Europe and America may be placed at between fifteen and twenty in each one hundred cases. And he declares that "the cold-bath treatment, rigidly enforced, appears to save from six to eight in each century of typhoid patients admitted to the care of the hospital physician."

As far as his own personal experience goes, and this is after all the great point of interest and importance to practitioners, Osler concludes as follows: "While I enforce the method for its results, I am not enamored of the practice. I have been criticised rather sharply for saying harsh words about the Brand system. To-day, when I hear a young girl say she enjoys the baths, I accept the criticism and feel it just; but to-morrow, when I hear a poor fellow (who has been dumped, like Falstaff, 'hissing hot' into a cold tub), chattering out maledictions upon nurses and doctors, I am inclined to resent, and pray for a method which may be, while equally life-saving, to put it mildly, less disagreeable."

After all our function, as Robert Smith said, "is not to make angels of men." We wish there were more observers like Professor Osler and that the average practitioner would read, mark, learn, and inwardly digest their teachings.

STUDIES FROM THE DEPARTMENT OF PATHOLOGY OF THE COLLEGE OF PHYSICIANS AND SURGEONS. Vol. IV. For the Collegiate Year 1894-1895.

THIS work, which is a collection of reprints of various articles printed in medical journals, proves two things: First, that this great institution of medical education has within its walls a corps of bright young men who are willing to devote hours of labor to original research which is not directly remunerative; and secondly, that the college encourages such work by setting upon it the seal of its approval and publishing the results to the world. The papers treat of subjects which are not speculative and theoretical, but are of intense practical value to the community. In most instances the work seems to have been done accurately and thoroughly, and the results are expressed clearly and concisely. Altogether it is a valuable contribution to medical literature.

INSANITY. Popular Errors Corrected, Summary Commitments, Inquisition, etc. An Address Delivered before the Society of Medical Jurisprudence, November 11, 1895. By HON. DAVID MCADAM, Judge of the New York Superior Court.

THIS address of Judge McAdam is a timely contribution to the literature of insanity, especially just now, when a popular interest has been aroused in the conduct of the various asylums to be placed under the control of the State. The prevailing notion that it is an easy matter to incarcerate a sane person in an asylum by conspiracy between relatives, physicians, and lawyers is shown to be disproved by the facts. The responsibility of the physicians is clearly defined and the difficulties in the way of a positive diagnosis are presented. With the address the society has published the lunacy laws of the State, some court decisions, articles by various authors bearing on the subject, and other matters of general interest to the profession.

ELECTRO-THERAPEUTICAL PRACTICE. A Ready Reference Guide for Physicians in the Use of Electricity. BY CHAS. S. NEISWANGER, PH.G. Chicago: E. H. Colegrove & Co. 1895.

THE book gives rules for guidance in the use of electricity in practice, principally as an adjunct to other therapeutic agents. All kinds of electrodes are illustrated, and the indications for the use of the different currents in the different ailments are given.

Therapeutic Hints.

Tinea Versicolor.—

R Hydrarg. chlor. corros. gr. iv.
Spt. vini rectificat. fl. ʒ vi.
Ammon. muriat. ʒ ss.
Aq. rosæ q.s. ad fl. ʒ vi.

Acute Pneumonia.—Now what part does cold play in filling these indications? It cannot fill them all, but it covers those of greatest importance. First of all it reduces the pyrexia, strengthens the pulse, tones up the heart, diminishes the pain in the chest, alleviates difficulty of breathing, and gives greater general comfort to the patient. It is capable, however, of doing

a great deal more. In virtue of its power to stimulate nerve function and to contract small blood-vessels it promotes the pulmonary circulation, relieves stasis, hastens resolution, and disperses the products of exudation. Strychnine in large doses to sustain respiratory and cardiac innervation; concentrated food of the most nourishing character, like fresh beef-juice, milk, brandy, etc., to support the constitution; digitalis to maintain the heart; oxygen by inhalation to relieve the breathing; morphine to produce sleep: ice-cap to the head to diminish restlessness; and strapping of the chest in case of great pleuritic pain, are some of the agents which will fill most of the remaining indications.—MAYS.

Trachoma.—1. Trachoma is an infectious and contagious disease which predominates in uncivilized countries and tends to disappear with the progress of civilization and of hygiene. Hygiene and cleanliness are the best preservatives against trachoma. 2. Trachoma is not influenced by altitude; it may spread wherever the people are uncleanly and live in poverty, quite as easily at altitudes of from 1,000 to 5,000 metres as on plains. 3. All races are equally susceptible to the virus of trachoma. An immunity for certain races does not exist.—VAN MILLIGEN.

Bed-sores.—Bed-sores may be aborted if, as soon as the skin reddens, a solution of nitrate of silver of the strength of twenty grains to the ounce is applied with a brush to the part. This measure fails in paralytics.—HARE.

Balsams in Eye Disease.—Balsam Peru and tolu in the form of one to three per cent. ointment are useful in ciliary blepharitis, superficial keratitis, corneal opacities, phlyctenular keratoconjunctivitis, superficial corneal ulcerations, deep ulcers with iritis, hypopyon, and other affections. The remedies are well borne, have an antiphlogistic and antiseptic action, and they serve as excellent cicatrizants, especially for the cornea.—G. NORSA.

Asafetida is a direct sedative to the pregnant uterus and exercises no evil influence over the general system. It is of particular value when abortion is imminent, as it controls uterine irritability. On the other hand, it is of no use as a prophylactic agent in such cases and must not be relied upon when the abortion has proceeded so far as to require manual interference. In habitual constipation and in nervous conditions during pregnancy it is highly beneficial.—WARMAN.

Laryngismus Stridulus.—

—DA COSTA.

Cardiac Affections.—The following are common in girls about the age of puberty: 1. Nervous palpitation and paroxysmal tachycardia in otherwise healthy individuals appearing premenstrually and lasting a short time after the flow. 2. Heart troubles which in chlorotic girls are occasioned by the phenomena of puberty. 3. Heart hypertrophy, developing slowly until puberty, then accelerating, because of disturbances of circulation, unhygienic clothing, or extraordinarily rapid growth of the individual.—KISCH.

Typhoid Fever.—1. Chlorine can be safely administered until complete disinfection of the alimentary canal is obtained. 2. Under its use the tongue becomes cleaner, the appetite and digestion improve, fever declines, and the stools lose their offensive odor. 3. The general strength, the intellectual processes, and nervous conditions improve. 4. The disease is shortened in duration, and usually proceeds to rapid and complete recovery.—WILCOX.

Angina Pectoris.—During the paroxysm nitro-glycerin, nitrite of amyl, chloroform, and morphine. During the interval most careful and abstemious diet, especially toward evening. Vascular stimulants in combination with cardiac tonics, especially arsenic. Exercise is to be avoided, and undertaken only when duly prepared for by the ingestion of some vascular stimulant.—BALFOUR.

Milk Filtered through Cotton.—Dr. Seibert, of New York, has made a number of experiments with milk filtered through cotton. He finds that while the greater part of the germs are eliminated no cream is lost. Plain milk showed from thirty-eight hundred to two hundred thousand germs, while the same milk filtered showed about one-fourth that number. If this is true, filtration is about as good as sterilization and has an advantage in that sterilized milk is not so good a food as plain milk.—*Canadian Practitioner*.

The Treatment of Diphtheria with Antitoxin.—Dr. Eulenburg reported at a meeting of the Berlin Society for Internal Medicine that of 10,240 cases of diphtheria 5,790 were treated with antitoxin with a mortality of 9½ per cent.; the remaining 4,450 were treated without antitoxin with a mortality of 14.7 per cent.—*Medical News*.

Common Salt for Ringworm.—Dr. F. J. Reilly concluded from the fact that children suffering from tinea tonsurans soon improve if sent to the seaside, that common salt would be good in the treatment of ringworm. He accordingly treated three successive cases in this way with remarkable success; a cure being effected in less than four weeks. A strong solution of sodium chloride was applied for five successive nights, washing it off in the morning with boric acid.—*British Medical Journal*.

Irrigation of the Peritoneal Cavity.—Dr. John T. Pitkin, of Buffalo, N. Y., thinks that whenever the general peritoneal sac becomes the receptacle of a purulent discharge from an hepatic abscess, from a suppurative mesenteric gland, from a pyosalpinx not radically removed, from a pyothorax via the diaphragm, and from suppurative peritonitis local or diffuse, the umbilical fenestra should be opened and a soft-rubber drainage tube inserted. This should be followed by repeated irrigation *ad lib.* with warm, sterilized, normal saline and antiseptic solution.

Fibroid Tumor of the Uterus.—Dr. W. Easterly Ashton finds that for the pains vaginal injections of hot water twice a day, followed by the introduction of cotton-wool tampons saturated in a ten-per-cent. solution of ichthyol in glycerin, are useful. The tampons are inserted two or three times a week and removed on the following morning. He also gives tincture of cannabis indica along with the bromide of sodium.

Hay Fever.—Dr. W. F. Strangways advances a new theory to explain hay fever (*Physician and Surgeon*, January, 1896). The author denies the commonly accepted theory that hay fever is due to the irritation caused by the impact of pollen in the nares of a neurotic person with some peculiar pathological condition of the upper air passages. His objections

to this theory are that the pollens that cause hay fever are very light and are never found in comparatively large quantities. The irritation caused by them cannot be so great as that caused by dust, yet hay-fever patients may be unaffected by even large quantities of dust. Blakely says that the largest number of pollen grains deposited in one day on a contrivance which he devised for the purpose was eight hundred and eighty. From this we calculate that scarcely one thousand grains of pollen enter the nares in a day, which would be but one grain for every twenty-five inspirations. If there were one hundred times as many they would not cause sufficient irritation to excite a coryza. Again, if the cause is a mechanical irritation it is hard to explain why one person is affected by rose pollen and not by rag weed and *vice versa*. Then, too, when hay fever attacks a man he ceases to breathe through the nares on account of the partial or complete stenosis, consequently the pollen is not drawn into the nose; yet the hay fever continues.

The new theory advanced by Dr. Strangways claims that hay fever is caused by a toxin generated from pollen by a fermentative process in an alkaline solution. It is possible that this toxin may be generated from other substances than pollen. Pollen may simply supply the microbe that generates the toxin from substances belonging to the nares of hay-fever subjects, and it is possible that other substances than pollen may convey such a microbe into the nares. This toxin produces a vasomotor paresis with paroxysms of sneezing. Some pathological lesions of the nose may predispose to hay fever by causing altered secretions suitable for the fermentative process and by causing a sluggish circulation and thus lessening the normal inhibitory powers. It seems possible that in pollen there are certain protoplasmic elements which in warm alkaline solutions change into the toxin causing hay fever.

Eggs.—A mustard plaster made with the white of an egg will not leave a blister.

A raw egg taken immediately will carry down a fish bone that cannot be gotten up from the throat.

The white skin that lines the shell of an egg is a useful application for a boil.

White of egg beaten with loaf sugar and lemon relieves hoarseness—a teaspoonful taken once every hour.

An egg added to the morning cup of coffee makes a good tonic.

A raw egg with the yolk unbroken taken in a glass of wine is beneficial for convalescents.

Theory to Account for Melæna.—Loranchet attributes melæna to the gradual chilling of the surface of the body after birth. The cold acts as a general debilitant and depressant of the nervous system; general circulation is disturbed; peripheral circulation is slowed; the vasomotor system is unbalanced. The change from the splanchnic cycle of the fœtus to the cardio-pulmonary cycle of the new-born infant is interfered with, and in the struggle of the reflexes there is a reversion to the splanchnic cycle with passive congestion of the gastro-intestinal mucous membrane, which gives rise to the hemorrhage.—*Gazette Heb. de Méd. et de Chir.*, 1895.

Corneal Ulceration.—In cases of corneal ulceration occurring in the course of keratitis, ophthalmia neonatorum, or gonorrheal ophthalmia take care in separating the eyelids to press upon the edge of the brow and not upon the eyeball, as pressure on the eyeball may cause perforation of the cornea, extrusion of the lens, and sometimes loss of a considerable quantity of vitreous humor.

(From our Special Correspondent.)

OBSCURE RENAL PAIN—DEMONSTRATION OF THE NEW PHOTOGRAPHY AT THE MEDICAL SOCIETY—PROTECTION OF THE PROFESSION—THE DEFENCE UNION AND THE B. M. A.—CURIOUS EDITORIAL RECANTATION—PAVY VERSUS PATON—DISCIPLINE—DISCUSSION ON PARASITES OF MALARIA (CONTINUED).

LONDON, February 28, 1896.

At the Medical Society meeting on Monday Mr. H. Fenwick read a paper on the aid afforded by the painful manifestations in determining the position of stone in the kidney. He said that when located in the pelvis there are frequent attacks of colic with radiation of the pain accompanied by irritability of the bladder, but when the stone is embedded in the cortex these symptoms are oftener absent. Again, with a stone in the pelvis of the kidney the patient can lie on the opposite side, but when it is situated in the pyramids he can sleep only on that side. Furthermore pelvic stones usually cause pus in the urine within a year or so, but embedded stones may be present twenty or more years without doing so.

A paper by Dr. Rolfe followed, in which renal pain was considered from a medical in contradistinction to the surgical point of view. He separated cases in which the pain is due to reflex nervous influence from aching kidney. The reflex cases are met with in valvular disease of the heart, especially when the aortic valve is involved; also in aneurisms, both thoracic and still more frequently abdominal.

Aching kidney he considered to be usually due to floating kidney, or tight lacing, or excess of some constituent of the urine, especially of acidity.

But the *piece de résistance* at this meeting was a demonstration of the new photography by Mr. Sidney Rowland. He began with the electric spark and showed that it was affected by diminution of the pressure of the air through which it is passed, and that when exhaustion is, as far as practicable, complete the character of the discharge is altogether altered. The utilization of discharges *in vacuo* was then enlarged upon. Crookes' tubes were shown and various experiments performed. That mechanical energy may be obtained from the cathode rays was shown by the revolution of a mica vane, and this accords with Prof. J. J. Thompson's theory that the impact of these rays on the glass is the point of evolution of "X" rays.

The Tesla method was considered the best at our disposal if only the tubes can be made to bear the strain. At present only a few have been equal to it. The probable applications to practice were considered by Mr. Rowland, who announced that by a new plan of preparing sensitive plates he had succeeded in obtaining a picture of the skeleton of a hand in only twenty seconds.

The protection of the character and interests of practitioners concerns the public as well as the profession. It is not likely, however, to be attained to any reasonable extent except by union among ourselves. The necessity of such union has been shown by the ruin which has too often overtaken individuals. The Medical Defence Union has made itself felt and the annual report for the past year shows that its work has been most valuable. In several cases it was no sooner known that the union undertook the case than redress followed. The report touches on the subject of amalgamation, on which I have previously written, and it is pleasant to learn that there is "every possibility"—I wish it were probability—of this end being accom-

plished. It is absurd to waste strength in two organizations, and unless the amalgamation is speedily effected the members of the "London and Counties" would do well to transfer their support to the union. Similar action might be taken by those who have supported small local societies, which cannot expect to obtain the power and influence of a central society with large funds. In this connection a somewhat unexpected development has taken place. For a long time certain members have urged that the work of defence ought to be taken up by the British Medical Association. The notion has been met by an obstinate *non possumus*, fortified by counsels' opinions as well as by an exhibition of pretended horror at the fear of confounding the association with a trades union. The *Medical Journal* has, of course, held this policy of the leaders and repeated every argument in its favor.

Now, however, the editor announces his conversion which, however, he does not admit to be a sudden change. He declares he has held for years the opinion that the association should undertake the work of protection and defence of its members, and he now declares that all the legal impediments hitherto insisted on can be easily overcome. He is careful, however, to signify that this recantation is purely personal and only his editorial confession. So, whether it will carry conviction to the rulers or is only a straw thrown up to show which way the wind blows, remains to be seen. This somewhat curious incident reminds me that when the editor was appointed, in the course of a discussion of his merits at a club where we met, it was most forcibly laid down by one of the ruling spirits and assented to by others that they were taking a man with no opinions of his own and who would always advocate theirs. I smiled then and have often laughed since at the recollection, which appears with renewed distinctness at this fresh development. We had a pleasant enough meeting in that club. Alas, that the intervening years have carried more than one of those present over to the majority.

If the British Medical Association should take up defence heartily, its great pecuniary resources would be of enormous advantage, but if it is not done *con amore* no good need be anticipated. There is something in a remark made at the meeting of the Defence Association, that their officers were experienced in the matter. But perhaps these could be retained in the event of amalgamation. It seems, too, that about a third of the members of the Defence Union do not belong to the association, and some members of the latter might oppose the project. In any event a year or more will elapse before the association can be at work and in the mean time the union is doing good work. Let it then persevere and decline to amalgamate until certain that it would be wise to do so.

A pretty critical duel is going on about the glyco-genic function of the liver. You know that Dr. Pavy has always repudiated C. Bernard's views and his recent book on the carbohydrates has brought out a sturdy opponent in Dr. Noel Paton. There have been some smart personal hits and each denies the other's facts. Dr. Paton writes in the *Edinburgh Journal* and Dr. Pavy in a London publication, which is rather awkward for some who do not see both regularly.

The Medical Council has elicited that most of the corporations possess disciplinary powers which might well be exercised over their licentiates, etc. The powers differ much in the various bodies, but most of them have hitherto been left in abeyance. We shall see what we shall see.

The adjourned discussion on the "Parasite of Malaria" was opened by Dr. George Thin at the ordinary meeting of the Royal Medical and Chirurgical Society with an account of the appearances found in the

tissues of a fatal case of pernicious malaria at Sierra Leone, illustrated by an interesting series of microscopic preparations. The temperature was 100° F. when the patient was first seen; during the night it rose to 106.2° F. On the second day it was 98.4° F. On the third day it rose to 106° F., and was brought down by treatment to 102.4° F. He died on the morning of the fourth day. The cerebral functions were disturbed when the patient was first seen and he soon became comatose. Surgeon-Captain Duggan sent Dr. Thin portions of the tissues. Brain: The vessels of the pia mater were congested, with some colloid-looking plugs penetrating the surface of the brain, apparently in the tracks of the vessels. The substance of the brain itself seemed to be little changed, but the blood-vessels contained many parasites of malaria. The large vessels contained very few and many none at all, but the small vessels contained many parasites and many capillaries were filled with them. The parasites were in the red corpuscles and were found in all stages of development. The most numerous forms were those which were in a very early stage, appearing a little more than a stained point in the centre of the red corpuscles. Others were of an intermediate size, occupying an appreciable extent of the corpuscle. Others, much fewer in number, had a comparatively large mass of central pigment and almost entirely filled the red corpuscles. The tissues not being in a perfect state of preservation, the finer structure of the spores of the mature parasite could not be observed. Spores in various stages, from the smallest forms to those of central pigment, could in some instances be found in the same vessel. Some of the endothelial cells of the vessels contained pigment. Spleen: All the sections examined contained many white corpuscles laden with pigment. These pigment-bearing cells were most numerous in the spleen pulp. Many of the very large white corpuscles which contained considerable blocks of pigment were evidently undergoing degeneration, their nuclei being scarcely susceptible of staining. A few of the white corpuscles contained, in addition to small pigment spheres, red blood corpuscles with parasites in their interior. The small lymphoid cells of the spleen did not contain pigment and very little of it was observed in the Malpighian corpuscles. The red blood corpuscles in the spleen contained very few parasites. Several were observed after a long examination. They were in an early stage. Large white corpuscles containing pigment were observed in the veins. Bone marrow: In a few sections of bone marrow examined some white corpuscles containing pigment were observed, but they were few in number compared with those in the spleen. No parasites were observed in the bone marrow. The marrow was from a rib. Liver: Parasites were not observed in the liver so far as the examination had gone, but it presented much pigment. The pigment was contained in large white corpuscles in the interlobular network. In some parts the liver cells contained pigment. Apart from the deposit of pigment the liver seemed normal. Kidney: All the structures of the kidney in the parts examined were normal except the convoluted tubes. In these tubes the epithelium was swollen and granular; some cells were broken down and in many of those which were still entire the nucleus refused to stain. These were in marked contrast to the straight tubes, which were quite normal. The glomeruli presented nothing abnormal. A few cells containing pigment were observed in them. There were no evidences of an interstitial congestion, the morbid appearances being limited to those of an acute catarrh of the convoluted tubes. No parasites were found in the tubes, and extremely few were observed in the red corpuscles in the vessels. The appearances suggested that the toxic products of the parasites, while being eliminated by

the kidney, had exercised a destructive effect on the epithelium of the convoluted tubes. All these appearances were similar to those described by Marchiafava and his pupils in the pernicious fever of southern Italy.

Dr. John Anderson referred to a very valuable paper in the Johns Hopkins Hospital Reports for last year, in which were recognized the usual types of malarial fever associated with three forms of parasites by Dr. Thayer and Dr. Hewetson, who do not altogether agree with Dr. Thin. It should be remembered that some sudden seizures might really be due to heat apoplexy, in which the hypodermic administration of quinine had often proved useful. The length of time during which the fever might remain latent varied in an extraordinary degree. In one case the malaria occurred nineteen years after the exposure to a last attack. In a case under his own observation an officer resided at Peshawur for five years and had no fever there, but after his return to England he suffered from ague resembling the ague of the Peshawur valley. He quoted an instance in which in a battery of horse artillery every man was attacked. A patient who left China twenty-three years ago and had not resided in a malarial country since, still suffered from malaria occasionally. Another patient suffered from brow ague, and yet it was forty years since he left a malarial country; this brow ague yielded to the free use of quinine. As to the method of propagation—whether by air, water, or mosquitoes—it was stated that when soil had been turned people had been attacked who lived in houses in a line with wind blowing from the soil. There were several cases to support the water-borne theory. There was certainly less disease at Peshawur since better water had been introduced. Water served as a vehicle not only when drunk, but in the form of inspired watery vapor. He thought that a point against the mosquito theory was this, that as a rule the recent arrivals in India suffered from mosquito bites, while those who had been there a little time appeared to suffer most from malaria. Cases of malaria with cholera features were sometimes difficult to discriminate; the malaria had a much less mortality than cholera; the disease was not epidemic and it was cured by quinine. In central India in three years six cases of severe sudden intestinal hemorrhage occurred; two of them died, but no intestinal ulceration was found. As a prophylactic he recommended a small dose of quinine daily. The hydrochlorate of quinine was the most suitable preparation, and if administered subcutaneously with antiseptic precautions gave rise to nothing but slight local pain. He had found iodine and arsenic valuable.

Dr. Manson, who showed microscopical specimens to illustrate his views, thought that the forms which had been described were not natural but factitious, and due to the rupture of the blood corpuscles and the escape of the parasite. Sometimes a parasite escaped voluntarily as a vital fact, and then gave birth to flagella; sometimes double infection of a corpuscle happened and conjugation of the parasites took place. He did not think that the mosquito acted as the intermediary host, for these parasites passed from one definite host to another. The flagellate bodies appeared in the blood only when the latter had escaped from the vessels; they were the homologues of spores and they swam about free from the parasite. The function of these bodies lay outside the human organization, and they were brought from outside by something that preyed upon the blood, and most likely the mosquito was the agent required for giving the parasite the opportunity for continuing its life history outside the body. In the mosquito the crescent bodies developed flagella, and these broke free and swam about in the blood in the mosquito's stomach. The parasite

of the pigeon was specifically different from that found in the human body. He could not entertain the idea that the flagellar movements were "death agonies," for the movements were most lifelike. He knew from personal observation that mosquitoes did bite birds, and canary fanciers in India were in the habit of protecting their charges at night with a mosquito curtain. In favor of the water-borne theory was the fact that the natives would point to certain wells as sources of malaria. He believed that the malaria parasite died in a very short time, for epidemics soon ceased. He concluded by deprecating the study of these organisms from the bacteriological standpoint. They were protozoa, and it was not necessary to study the stained parasite when the living animal could be obtained to look at.

Professor Cayley (Netley), who remarked that he had come to hear something more of the relation which a special form of parasite bore to a particular variety of malarial fever, but had heard very little that was certain on that point, believed that all the varieties were but modifications of the same parasite; similarly, all the forms of malarial fever were merely modifications of one type—modifications by climate, by temperature, by the quantity of the parasite introduced, by its virulence, and by the power of resistance of the individual. One particular form of microbe was invariably found, the amœba; two or three in a field might assume the rosette form and sporulate, and thus give rise to another generation of microbes. The differences of shape he believed to be accidental; the sporule might gradually become pigmented, and the pigment be aggregated or scattered. Most of the flagella appeared to be found when the fever had taken on a chronic form. He believed quinine should be given in the sweating stage and repeated in the next few hours; this prevented recurrence. It never would prevent an attack if given before it. As to its use as a prophylactic, he believed in a five or ten grain dose every morning, and the late Surgeon-Major Parke found it simply invaluable when so used in Africa.

Brigade-Surgeon Lieutenant-Colonel Temple Wright, who served in Indian regiments composed of different classes of natives, could say that malarial fever was the chief cause of invalidism and that most of the soldiers admitted to hospital had large spleens. He believed that exposure had a good deal to do with the exciting cause of malaria. In treatment he believed that antiscorbutic measures were useful when combined with quinine.

Dr. Galloway thought that the study of the protozoa was still in its infancy and that we had only histological examinations on which to rely; therefore he deprecated dogmatic statements with reference to the stages of these organisms, especially when such statements referred to negative results. The experience gained in the study of coccidium oviforme should not be lost upon investigators. He had convinced himself that flagellar movement was a vital and not a degenerative process.

Brigade-Surgeon Scriven said that the chief difficulty in India was to decide whether the fever was typhoid or malarious, and perhaps the parasite would help to decide this point. He quoted a remarkable effect of change of air. A patient living in a malarious district and contracting malaria might move to another more malarious district and yet get rid of his malaria. This seemed to point to a parasite of a different kind. He thought there was evidence that the parasite might be contracted through water.

Fissure in Ano.—The more I treat fissure the more I am satisfied it can be cured by slight dilatation, often by means of a small speculum, dilating until slight pain is evinced, and in the majority of instances the fissure disappears.—MATTHEWS.

OUR PARIS LETTER.

(From our Special Correspondent.)

TYPHOID FEVER SUCCESSFULLY TREATED BY SEROPATHIE — DESQUAMATION — SEINE WATER OFTENEST THE CAUSE—EARLY DIAGNOSIS BY MEANS OF BACTERIOLOGICAL EXAMINATION OF DEJECTA, ETC.

PARIS, March 1, 1896.

THERE is perhaps no disease that interests and threatens the public health more directly and as constantly as typhoid fever, whether in epidemic, endemic, or sporadic form. Owing to the efforts of the municipal government to supply the city of Paris with pure, uncontaminated drinking-water, the danger has been partially averted, as the continued low death rate from typhoid fever has shown during the last few years as compared with that of preceding years. Nevertheless, every summer the water of the river Seine is turned into the pipes to be used as drinking-water, and although the inhabitants are duly warned beforehand and cautioned to boil their water before drinking, thousands neglect this precaution and we therefore see a recrudescence of the disease shortly after. Filtering alone is of very little use, for, as is well known, the bacillus of Eberth passes uninjured through the best-made filters. Boiling is sufficient, but boiling first and filtering afterward is best, as boiling alone destroys the microbes but leaves their cadavers in the water. If this then be filtered it becomes absolutely pure and innocuous. It should not be forgotten, either, that milk is often the vehicle of typhoid fever, not so much because the milk itself contains the bacillus when taken from the cow, which is sometimes the case, but because it is before selling diluted with typhoid water. We consider the bacillus of Eberth the pathognomonic characteristic of typhoid fever, because it is always to be found in the dejections of typhoid patients if properly sought for. This has been demonstrated effectively by Professor Chantemesse, of the Faculty of Medicine of Paris, in a paper read at the last meeting of the Biological Society. And who is better qualified to speak on a matter of such great hygienic importance than he who is the *chef de service* at the Institute Pasteur (*médecin des hôpitaux*), and who edits the chapters on typhoid fever that appear in almost all our contemporary works on the practice of medicine. He now proposes to generalize his method of early diagnosis of typhoid fever by the bacteriological examination of the dejections and to treat the disease itself *ab initio* by the famous seropathie. What results he has already attained we shall presently see. Professor Elsner has recently discovered a new procedure for the culture of the typhoid bacillus. The antiseptic that permitted him to cultivate the bacillus of Eberth, while preventing the development of other microbes, is the iodide of potassium. Professor Chantemesse utilized Professor Elsner's method to look systematically for the bacillus of Eberth in the dejections of persons in good health, of persons affected by different maladies, and of patients with typhoid fever. He examined the dejections of two persons in good health, of one patient with erysipelas, of two with grippe, of one other with pleuritis, and none of these examinations ever showed the presence of typhoid bacilli. He then submitted to the same analysis the dejections of sixteen patients who had had or who actually had typhoid fever; in thirteen cases the results of the analysis were positive; in three cases only were they negative. But as to those three cases Professor Chantemesse hastens to add that the absence of the bacillus of Eberth can be explained by an error of technique. It will be seen then what great service this method will render in making an early diagnosis of typhoid fever. Moreover, we shall be

able to employ at once a specific treatment that has been wanting up to the present time; we refer to the seropathie of typhoid fever.

Let us hear a moment Professor Chantemesse: "I must say in this connection that since the month of June, last year, I have immunized several horses against the typhoid virus. The serum that I obtained possesses a preventive power so great that one-fifth of a drop with which a guinea-pig was inoculated twenty-four hours beforehand protected it efficaciously against the dose of typhoid virus which was mortal for the other animals" (non-inoculated and serving as witnesses). Now for the application to man: "After having assured myself that this serum was preventive and curative for animals and that it had no bad effects whatever, either on them or on man in good health, I utilized it in treating three typhoid patients having the bacillus of Eberth in their dejections. Seven days after the beginning of the injections these three patients were restored to health."

It would indeed seem that we are really touching with our hands the realization of a rational treatment of this terrible disease, a treatment at once easy to manipulate, efficacious, and specific.

The days of heroic drugging in typhoid fever have long since been numbered, and experience has shown how much more is to be gained by relying upon rest, wines, milk, brandy, at times; at others, quinine and disinfection of the intestinal tract by means of salol. Seropathie will relegate to disuse the much-vaunted cold baths, which are a real torture for most patients but to which they have been obliged to resign themselves, as it was the best treatment hitherto known. While upon this subject it is worthy of note that at the Hospital Trousseau last year in thirty-one cases of typhoid fever desquamation was observed when looked for carefully in all except two mortal cases and occurred at the defervescing period. This desquamation is, however, not confined to typhoid fever alone, but may also be observed in other acute diseases in which we would not expect to find it, such as pneumonia, pleuritis, rheumatism, etc., being due to sudor sudaminis and having no wider semeiological importance.

It is to be hoped that we shall soon have fuller data regarding the number of injections used in each individual case, exact quantity of the serum employed, and its strength. When the ordinary duration of typhoid fever is reduced from twenty-one, twenty-eight, thirty, or even forty days to seven, we may truly say that medicine is approaching magic.

INJECTIONS INTO THE TESTICLE FOR THE CURE OF PROSTATIC HYPERTROPHY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: A few weeks ago there appeared in the MEDICAL RECORD an article recommending as a measure of relief for the cystic troubles resulting from enlarged prostate the injection of cocaine into the body of the testicle. It was claimed for this treatment that "it is not severe and is effective"; further, "that the secretion of spermatozoa is arrested," etc. I have not demonstrated by trial the fallacy of such treatment nor do I care to do so. There can scarcely be a doubt that malignant disease and inflammatory troubles may in rare instances follow.

It would seem clear to most minds that unless orchitis ensues the testicle will continue its function as soon as the effect of the cocaine disappears. A suppository in the rectum would do as well. Orchitis when severe enough will arrest the sperm. But what of that? Who would care to risk it in a feeble old man?

Besides, where would be the gain, since the testicular fluid would be produced and fill up the vesiculæ as before? Castration most probably has its *rationale* in the atrophy and disappearance of the vesiculæ seminales and not in any change in the prostate. These vesicles extend at right angles to the prostate antero-posteriorly across the bladder. When full of semen, as they are in old men most of the time, they act as a stay against the contraction of the base of the bladder and thus prevent the complete emptying of the viscus.

No opportunity has occurred to me to verify the above suggestion. It may readily be done upon the cadaver by injecting the vesiculæ to the point of distention and ligating the exit. If the suggestion proves this to be a fact, castration may be relieved of its opprobrium and further trial continue to prove its value.

R. W. ERWIN, M.D.

DAY CITY, MICH.

WHAT IS AMATEUR SURGERY?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your correspondent in last week's issue takes exception to my use of the words "amateur surgery" as applied in discussing Dr. Delavan's paper on cancer of the larynx.

He complains that my expression was "meant to be severely condemnatory" and asks "is there really such a bastard entity as a professional amateur?"

My own words as reported were as follows: "It is easy to remove a cancer of the tongue; it is almost impossible to prevent its recurrence. The study of the lymph channels and removal of all infected glands in a case of this character has given the subject a new impetus, and, while it places a cure within the range of possibility, it at the same time removes the operation from the field of amateur surgery. The same remarks apply to cancer of the larynx."

After the meeting I was thanked by several members for having taken the stand against men of no special surgical training attempting to do operations of gravity, and was told there were some men present "squirming in their seats at the recollection of a fatal case recently bungled over by them which they ought never to have dared to touch."

Contrary to your correspondent's views I believe there is a considerable amount of grave surgery done to-day by practitioners whose temerity is stimulated by inflated statistics of small mortality under modern surgical practice, and whose feeling that they would like to do serious surgery is entirely unjustified by their training. Such novices in the larger field of work are rightly called amateurs. They may be professional men but they are amateur surgeons.

Your correspondent is apparently unaware of the fact that there is more than one legitimate use of the word amateur. The usual acceptance, which he understands, means simply the opposite of professional, or one who does not win money by work.

There is, however, another that is mentioned by Littré, the greatest authority on the French language, and described as follows: "Derogatively, 'he is an amateur,' that is to say, he is a man of mediocre talent."

That is precisely what I wished to convey in speaking as I did. No man of mediocre talent or training should attempt operations involving grave risk to human life and obviously beyond his depth. He should confine himself within minor surgical limits.

I think your correspondent will agree with me that such men exist, and if he does, that there should be a word said to cut short that sort of work.

ROBERT ABBE, M.D.

NEW YORK, March 12, 1896.

TYPHOID FEVER IN INFANTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial in the issue of February 29th prompts me to report an experience of two cases of typhoid fever in infants of fifteen and eighteen months of age. The former case was observed in November and December last, and presented the following well-marked signs of the disease: Continued fever with morning remissions, nose bleed during the first week on two occasions, abdominal distention, moderate diarrhoea with characteristic stools, rose-colored spots upon the abdomen and chest after the seventh day, palpable spleen. The urine on the application of Ehrlich's test at two different examinations showed distinctly the diazo reaction, which disappeared after the cessation of fever. The highest temperature recorded was $104\frac{2}{3}^{\circ}$ F. in the axilla on the twelfth day. The entire duration of fever was about twenty days. In the management of the fever I was agreeably impressed with the effect of the cold-water coil applied to the abdomen, which was placed when the thermometer was found above 102° F. For instance, the chart one day showed a temperature at ten o'clock of $102\frac{3}{4}^{\circ}$; the coil was placed and the temperature at 11:30 was $101\frac{2}{3}^{\circ}$ F.; the coil was then removed. At 1:30 the temperature was $104\frac{2}{3}^{\circ}$ F.; the coil was placed, with iced water running; at 2:30 the temperature was $100\frac{1}{4}^{\circ}$ F. and the coil was removed. At 5:30 the temperature was $103\frac{1}{2}^{\circ}$ F.; the coil was placed; at 6:30 the temperature was 100° F., when the coil was removed. At 8 the temperature was $103\frac{3}{4}^{\circ}$ F.; the coil was placed; at 9 the temperature was $99\frac{1}{2}^{\circ}$ F.

There was much emaciation and some bronchial catarrh. On inquiry it was ascertained that there had recently been a case of typhoid fever in the family of the milkman who supplied a part of the neighborhood in which my case occurred, but no others were traced.

The other case, a child eighteen months old, I have not the notes of, but the symptoms were sufficiently distinctive to warrant the diagnosis. It occurred several years ago, the child having been at a summer hotel in the country for a few weeks and brought home with a fever. This ran for about three weeks and was followed by a mitral regurgitation, which was still present four years later.

The query occurs: If it is shown, as seems to me it has been conclusively, that children under three years are not immune to typhoid fever, can it not be that the disease is more common than is supposed and is frequently overlooked? The common occurrence of continued fever with intestinal and bronchial catarrhs in infants, and the general teaching that typhoid fever is not found in these subjects, are apt to militate against a closer examination which might reveal typhoid fever more commonly. It seems to me that well-conducted foundling asylums would hardly be the place to look for the disease.

On looking up the literature at my command I find the following: Ashby and Wright, second edition by Northrup, page 278: "It is not common in children under three years of age, though it undoubtedly does occur even in infants, and may be fatal." Pepper's "American Text-book of Theory and Practice," vol. i., page 54, by Pepper: "It is far more general in early life than is usually recognized. Murchison reports its occurrence in an infant six months old, and Chancellay reports two cases in infants but a few days old, while several observers have discovered evidences of the disease in the foetus. I have observed several cases during the first year of life."

WILLSON O. BRIDGES, M.D.

118 NORTH EIGHTEENTH STREET, OMAHA, NEB.

Surgical Suggestions.

Gastro-enterostomy.—1. Gastro-enterostomy should never be performed in extremely cachectic patients. There is nothing to gain and much to lose. 2. The posterior wall of the stomach is the preferable locality for the approximation. 3. Supporting sutures, outside of the button, are not necessary, except for the relief of tension. 4. The peritoneum of the stomach should be scarified at the point of approximation, as union is thus hastened.—MURPHY.

Cholecystoduodenostomy.—The indications for this operation are (1) permanent obstruction of the cystic duct, (2) obstruction of the common duct, (3) cases of septic cholecystitis when a long period of continuous drainage is desirable, (4) cases of fistula of the gall-bladder when the patient is becoming emaciated from loss of bile.—MURPHY.

Umbilical Hernia.—The following cases should be subjected to operation: 1. Umbilical hernias of the new-born if strangulation occurs, or if persistent gastro-intestinal troubles are induced which seem to be dependent upon the hernia. 2. The hernias in children of from two to seven years present analogous indications. 3. Children of this age, belonging to poor families, who do not receive proper attention if at the end of a year or eighteen months the hernia is still of the same size. 4. Hernias that persist after the seventh year, that are rebellious to treatment and tend to increase in size. 5. If the skin covering the hernia is inflamed or ulcerated. 6. If the hernia interferes with the occupation that the person has selected. 7. Umbilical hernias with a large ring. 8. Those that are subject to strangulation or inflammatory accidents. 9. Those that cause pain and gastro-intestinal disorders, and consequently interfere with the development of the child.—CAHIER, *Revue de Chirurgie*.

Head Injuries.—The great bulk of the hemorrhage comes from the vessels of the arachno-pial membrane and of the temporo-sphenoidal lobe of the brain and not from the fractured bone. The path of the discharges is along the sheath of the auditory nerve through the lamina cribrosa to the vestibule, thence through the middle ear and the ruptured membrane to the external meatus. Excluding the extra risk of sepsis, the prognosis is on the whole better when these signs exist than when they do not.—MILES.

Epididymitis.—

R. Sodii bromidi,
Acidi borici.....āā ʒ viij.
Tr. aconiti..... gutt. viij.
Tr. belladonnae..... fl. ʒ i.
Liq. potassii cit..... q. s. ad fl. ʒ viij.

M. Sig. Tablespoonful three times a day.

—WHITE.

Appendicitis.—I am not always in a great hurry to operate, but I am inclined to wait for the more acute symptoms to wear off, and operate, if at all, after suppuration has taken place, or during the quiescent stage, between the attacks. I wish my voice was strong enough, just here, to call a halt to the men who say: "Operate at once—not this afternoon or to-morrow, but now," in all cases when the disease is recognized.—McGUIRE.

Incisions of Face.—Incisions made in the skin of the face should be placed where there is a shadow, or in the bottom of the furrows produced by the habitual expression of the patient. When this cannot be done, the incision should be parallel to the facial line rather than across it. A slightly curved incision makes a less conspicuous scar than a straight or abruptly curved one.—ROBERTS.

Stages of Ether Anæsthesia.—When produced by inhalation there are four stages of anæsthesia. (1) The stage of stimulation, characterized by excitement and a pleasing intoxication. (2) The anodyne stage, characterized by impaired sensation, retained reflexes, delirium, which is most marked in robust individuals, tetanic contraction of the muscles, turgescence of the face, etc. (3) The anæsthetic stage, characterized by the abolition of the ordinary reflexes and of all conscious excito-motor sensibility. (4) The paralytic stage, characterized by diminution of unconscious excito-motor sensibilities, and, finally, by death from paralysis of the respiratory centre.—JOHN CHALMERS DA COSTA.

Intestinal Obstruction.—Obstruction of the small gut gives rise to dysuria and there is usually an increased amount of indican in the urine, due to decomposition of albuminous matter, forming indol; while if the obstruction be in the large intestine, indican is not increased, as the albuminous substances are not present there in such quantity.—WILLIAMS.

Mucous Polypus.—Long-standing chronic catarrh of the hypertrophic variety causes the middle turbinate to return to is embryonic condition, that is, it becomes cleft in two portions running antero-posteriorly. Between this cleft, the blood supply not being sufficient, true mucous membrane is not formed, but in its stead a myxomatous structure accumulates, which by gradual enlargement increases the space thus formed and which in its final development is a true mucous polypus.—WOAKES.

Recurring Epistaxis.—Among the general causes of recurring epistaxis are: 1. Diseases affecting the blood-vessels or associated with alteration of the constituent parts of the blood, as in scorbutus, purpura hæmorrhagica, simple and pernicious anæmia, plethora, hæmophilia, malaria, and exceptionally in septic diseases such as pyæmia, septicæmia, etc. 2. Certain acute diseases, such as typhoid and relapsing fever, and occasionally in pneumonia, diphtheria, etc. 3. Diseases producing local or general vascular congestion, such as valvular disease of the heart, pulmonary affection, cirrhosis of the liver, chronic nephritis, amyloid degeneration, and mediastinal tumors. 4. It may be the expression of a vicarious menstruation, or, 5. May accompany the course of a pregnancy. Among the local causes may be assigned: 1. Tumors such as fibroma, carcinoma, and sarcoma, particularly angiosarcoma, fibro- and myxosarcoma. 2. Varicose enlargement of the veins, particularly on the anterior portion of the septum. 3. Perforating ulcer of the septum. 4. Trauma. 5. Local ulcerations caused by syphilis, tuberculosis, and lupus, and, finally, 6. Deformity of the septum, associated with erosion or ulceration of the mucous membrane of the septum.—VAN SANT.

Laryngeal Phthisis.—Surgical treatment is followed by relief of pain; there is ease of swallowing food, improvement of voice, cough, and respiration. The indications for curettage are: 1. In case of primary tuberculous affections without pulmonary complications. 2. In cases of concomitant lung disease, which is either in the incipient stage or has at least not progressed to softening and hectic conditions. 3. It is best adapted for circumscribed ulcerations and infiltrations of the larynx especially. 4. For the dense, hard swelling of the arytenoid region, the ventricular band, the posterior wall, for tuberculous tumors, and for the affections of the epiglottis. 5. In advanced lung disease with distressing dysphagia resulting from infiltration of the arytenoids, curettage is justifiable as the quickest means to give relief. Contraindications are:

1. Advanced pulmonary disease and hectic. 2. Disseminated tuberculous disease of the larynx, leaving little or no area of healthy tissue. 3. Extensive infiltration producing severe stenosis, when tracheotomy is indicated.—GLEITZMAN.

Ludwig's Angina.—The specific identity of the affection has always been a mooted point. Ludwig gave as its characteristic features: (1) A peculiar wooden induration of the tissues, not receiving impression; (2) a uniform spread of this induration in such a way that it is always sharply bordered by a zone of entirely unaffected cellular tissue; (3) a hard sublingual swelling with a bolster-like mass around the interior of the lower jaw of a deep red or bluish-red color. Treatment embraces early incision, subsequent rigid antisepsis, and general support.—JAS. E. NEWCOMB.

Anæsthetics.—Schleich holds that anæsthetics are more dangerous the more their boiling-points differ from the temperature of the body. He has devised an anæsthetic mixture (chloroform and petroleum ether) whose boiling-point is the same as the temperature of the body, and has obtained excellent results, all disagreeable sequelæ being absent.

Cocaine.—Réches always limits the strength of the solution to one per cent., and makes multiple punctures when using it hypodermically. He advises against its adoption in those suffering from hysteria or heart disease.

Iron not Necessarily a Large Ingredient in our Food.—Dr. Stockman tells us that the average amount of iron consumed daily by a person averages ten milligrams, and an analysis of the excreta shows a like quantity. He thinks this fact should be borne in mind by those members of the profession who are in the habit of prescribing large quantities of ferruginous tonics.—*Jour. of Physiology*, vol. xvii., p. 488.

Disinfection.—1. Washing with warm water and soap, with vigorous use of brush. 2. The same, with the addition of sand. 3. Washing with warm water and green soap, then scrubbing with carbolic acid. 4. The same, substituting lysol for carbolic acid. 5. The same, with tricresol. 6. Corrosive sublimate used in several ways. 7. Chlorine water. 8. Soap and water, permanganate of potash, and oxalic acid.—REIYECKE.

Asphyxia Neonatorum.—The method of resuscitation consists in suspending the child by the feet, the head being lightly supported. If no assistant be available to hold the child's feet, the operator grasps the ankles between the fingers of his left hand. With the right he grasps the chest, the thumbs being in front, and makes six to eight regular compressions; at first expiration, the nose and mouth are freed from any mucus, which allows air to enter with the inspiratory effort.—PROCHOWNICK.

Intussusception.—

R Tabaci ʒi.
Aq. bullientis Oi.
Macerate per sextum horæ partem, et cola. Sig. Inject one-quarter or one-half, and repeat in half an hour, if necessary, carefully watching its effects.

—GUY'S HOSPITAL.

Chloroform in Parturition.—It is the extraordinary development of the vasomotor and circulatory system that gives immunity to pregnant women, at parturition, from the evil effects of chloroform. This immunity does exist; less than forty deaths in the world, to date, from this cause, is proof enough. The doctor uses chloroform to relieve pain at any stage, to shorten labor by relaxing the cervix and perineum. He does this without disturbing the uterine contractions. He

also thinks that chloroform tends to prevent post-partum hemorrhage and lacerations. He gets great satisfaction from the use of chloroform in retained placenta, with contracted and rigid os and perineum. All parts are relaxed so that extraction is a matter of routine only.—BROWN.

Aphrodisiac.—

—LUTAUD.

Empyema in Children.—In cases of double general effusion, it is better to aspirate first on both sides, in order to diminish the quantity of fluid and relieve the heart from the incumbrance to its action. Next day operate on one side, and a few days to a week later operate on the other. The left side should be chosen for the first operation, and local rather than general anæsthesia employed.—CANTLEY.

Osteomalacia is a chronic disease peculiar to adult life, which leads to a gradual withdrawal of the earthy salts from all parts of the skeleton, and consequent softening and abnormal pliancy of the bones, with ultimate deformity of the trunk and limbs.—SENATOR.

Circumscisus.—Local indications: Hygienic, phimosis, paraphimosis, redundancy (where the prepuce more than covers the glans), adhesions, papillomata, eczema (acute and chronic), œdema, chancre, chancreoid, cicatrices, inflammatory thickening, elephantiasis, nævus, epithelioma, gangrene, tuberculosis, preputial calculi, hip-joint disease, hernia. Systemic indications: Onanism, seminal emissions, enuresis, dysuria, retention, general nervousness, impotence, convulsions, hysterio-epilepsy.—RICKETS.

Ear Piercing.—Fournier reports a number of cases of lupus, syphilis, and tuberculous nodules from ear-piercing as practised by jewellers. While such a small operation can be performed by almost any intelligent person, the needle should be thoroughly sterilized by heat and the skin washed.

Influence of Circumcision in Preventing Syphilis.—Total of venereal cases, not Jews, 272; gonorrhœa, 107; syphilis, 165; proportion of gonorrhœa to syphilis, 0.6 to 1. Total of venereal cases, Jews, 58; gonorrhœa, 47; syphilis, 11; proportion of gonorrhœa to syphilis, 4.3 to 1.—JONATHAN HUTCHINSON.

Local Anæsthesia.—

R. Chloroform	10 parts.
Ether	15 “
Menthol	1 “

The anæsthesia resulting from the application lasts about five minutes.—LE GERANT AND E. PIERRE.

Rules for the Surgeon to observe in order to prevent the absorption of poison during operations on septic patients: 1. After the hands and arms are made aseptic, dip them in strong ammonia water, or in a saturated solution of oxalic acid. This procedure will instantly reveal to the surgeon the least abrasion of the skin from any cause. 2. All small abrasions, or separations of continuity of skin, should be painted with flexible collodion, and immediately covered with a few fibres of absorbent cotton. Dry this dressing quickly with heat from alcohol lamp, and again paint with flexible collodion, and dry in the same manner. Then sterilize finger in 1 to 100 bichloride solution. 3. If the wounds are on the joints, apply a strip of adhesive plaster over the cotton and collodion dressing, passing

the plaster quite around the finger, at least twice. Fasten this dressing securely with thread. Or, instead of the adhesive plaster, draw on a rubber cot or glove. Sterilize finger or hand and dressing in 1 to 100 bichloride solution. 4. If the hand or finger is wounded during an operation, stop long enough to place on the wound a drop of saturated solution of carbolic acid, or lysol, or creolin, or touch it with a nitrate of silver point. Cover the wound with a small pledget of absorbent cotton, well saturated with carbolized or creolin water, and cover this cotton thoroughly with adhesive plaster. Fasten this plaster securely with thread. Sterilize the finger and dressing by immersing it in 1 to 100 bichloride solution, and proceed with operation. 5. Remember that your health is, or should be, as valuable as the patient's, and that if you have a good assistant to watch the patient, five minutes' time given to dressing your own wound will make no appreciable difference in the result of the operation you are performing.—HORACE T. HANKS.

The Curette in the course of acute gonorrhœa is one of the surest means of causing extension to the tubes and ovaries. The mucosa, acting as a barrier against microbic infection, having been destroyed, entrance of specific pus from the vagina sets up uterine gonorrhœa of aggravated type, and the parametrium is liable to invasion through open and damaged lymphatics. Enforce rest. Leave the uterine cavity alone. Swab vagina and cervix with a one-per-cent. silver solution once or twice per week. Inject a 1 to 1,000 sublimate solution twice daily.—AUVARD, *Arch. de Toccol.*, etc., June, 1895.

Treatment of Hemorrhoids.—Professor Roux speaks highly of the following treatment of piles: Place patient in the lithotomy position, and introduce the two thumbs into the rectum. Then, making semi-circular movements, gradually separate them, until, by dilatation of the rectum, they come in contact with the ischium. When the piles are brought plainly into view, take a hypodermic syringe, filled with a fifty to eighty per cent. solution of carbolized glycerin, and inject two drops of the solution into each pile, holding the base of the pile between the thumb and index finger, while the needle is entered near the anus and pushed to the base of the pile, not going directly through the mucous membrane. This is a precaution against bleeding, which is, however, very slight. Professor Roux thinks the good results are due rather to the dilatation than to the injections.—*L'Union Médicale*.

Forced irrigation or hydraulic curetting for ulcer and abscess of the cornea.—After cocaine separate the lids and throw a jet of an antiseptic solution against the ulcerative tissues by means of a syringe. Only diseased tissue is attacked.—SANTARNECCHI, *Ann. d'Oculist.*, September, 1895.

Vibrations are advised for subinvolution and other uterine diseases (Brandt and Kelgren's principle). They must be regular and penetrating and can be transmitted through the abdominal walls. A vibrator is fitted to a portable dynamo and placed with the right hand against the parietes, toward which the uterus is pushed with the left forefinger in the vagina. It is useful also in metrorrhagia due to fibroid.—BOURCART, *Anq. de Gyn. et d'Obst.*, June, 1895.

Treatment of Aneurisms by Extirpation.—Dr. Delbet claims that before 1888 the mortality was between eleven and twelve per cent., but in the 76 cases since reported there is not a single death. Of 109 cases treated by ligation 12 had gangrene, while of the 76 cases extirpated there were but 7 instances of this accident, and in 4 of these the gangrene existed before the operation. Recurrence is one of the dan-

gers of ligaturé, but it is much less apt to take place after extirpation, if indeed it is possible.—*Sem. Méd.*, October 30, 1895.

Sympathetic Ophthalmia.—After enucleation, bacteriological examination of nerve and globe were both negative. Any stimulation, however, of the ciliary nerves of one eye was followed by disturbances in the other which were appreciable under the microscope. They consisted in foci of fibrinous excretion and extravasation of blood corpuscles. Coagula of fibrin are probably the initial lesions in the production of sympathetic ophthalmia.—BASH, *Ann. d'Oculist.*, September, 1895.

Erysipelas.—

R Ichthylol..... ½ iiss.
Collodion flex..... ½ iiss.
M.

This was directed to be applied every three hours, always commencing the application about one inch beyond the line of demarcation, between the healthy and inflamed skin. I believe this to be of the greatest importance.—DEWITT.

Pernanganate of Calcium as an Oxidizing Agent.

—Nardas thinks permanganate of calcium superior to bichloride of mercury as an oxidizing agent. When placed in contact with organic matter it is immediately resolved into lime and manganese dioxide, giving off oxygen. It also has the advantage of being quite free from both caustic and toxic properties.—*Gaz. Méd. de Paris.*

Genu Valgum.—In the Macewen operation the incision is made vertically on the inner aspect of the thigh, and the bone divided "at a point where the two following lines meet: one drawn transversely, a finger's breadth above the external condyle, and a longitudinal one drawn one-half inch in front of the adductor magnus tendon." In the MacCormac operation the incision is made transversely on the outer aspect of the thigh at a point about two inches above the lower femoral epiphysis.—GRAVES.

Otitis Media.—Inflammation of the middle ear occurs most frequently as a complication or sequel of some other disease, and is the result, as we say, of extension of inflammation or perhaps, to speak more scientifically, of migration of bacteria from the throat or other outer parts of the respiratory system through the Eustachian tube to the tympanic cavity.—BALL.

Nearly all of the children who had died of bronchopneumonia showed otitis, and in thirty-three of the forty-three in which the secretion was rigidly examined the pneumococcus was present.—RASCH.

Operations on the Intestines are divided into the following classes: (1) Resections of the bowel for gangrene: *a*, for internal obstruction; *b*, for hernia; (2) resection of the bowel for the cure of fecal fistula; (3) resections for internal obstructions other than malignant disease; (4) resections for malignant growths; (5) resections for perforations of the intestine, traumatic or otherwise; (6) resection of the rectum; (7) Bacon's operation.—MURPHY.

Food Infection with Toxicogenic Germs.—The relation of the germ to the production of the untoward symptoms may, according to the case, be stated in one or the other of the following ways: (1) The chemic poison is generated only and wholly in the food before it is taken; (2) The infecting organism may begin the elaboration of its poisonous products outside, and continue the same within, the body; (3) The infection may not result in the production of poisons until the food is taken into the body.—VAUGHAN.

Medical Items.

Regulations Regarding the Isolation of Cases of Diphtheria in Private Houses by Health Department.—In private houses the duration of isolation of cases of diphtheria after apparent complete convalescence of such cases shall be determined by the physician in attendance, with the following conditions:

1st. Children convalescent from diphtheria shall not be allowed under any conditions to attend any kind of school; *i.e.*, day school, Sunday school, dancing-school, etc., until cultures show the absence of diphtheria bacilli in the throat.

2d. Circulars of information regarding the persistence of virulent diphtheria bacilli in the throats of convalescent cases of diphtheria and the dangers from infection arising from such cases shall be furnished by the Health Department and presented by the attending physician (if the patient is a child) to the mother, father, or guardian, or, if the patient is an adult, to the patient, and the meaning of the circular and the significance of its contents explained to them.

3d. The attending physician, when continued isolation is not maintained, shall immediately notify in writing the Chief Inspector of Contagious Diseases of the Health Department of his action, and disinfection of the premises may then be performed by the Health Department.

Exceptions to this rule regarding the time of isolation of convalescent cases of diphtheria in private houses shall be: (1) Teachers of all kinds. (2) Persons whose occupations bring them into immediate contact with children. The regulations of the Health Department regarding isolation of cases of diphtheria in boarding-houses, apartment houses, hotels, and tenement houses heretofore observed shall be continued. [Signed] GEORGE B. FOWLER, M.D., *Commissioner of Health*. By order of the Board of Health. CHARLES G. WILSON, *President*; EMMONS CLARK, *Secretary*.

Circular of Information Regarding the Danger of Cases of Diphtheria Communicating the Disease to Others after Convalescence.—Diphtheria is due to a germ known as the diphtheria bacillus. This germ is present in the membrane and in the secretions of the mouth, nose, and throat of cases of diphtheria. The disease is only produced by the reception of these germs into the mouth or air passages of other persons. The discharges from the nose and throat of cases of diphtheria containing these germs may be received on handkerchiefs, towels, bed clothing, carpets, rugs, personal clothing, toys, books, etc., dry, become pulverized and breathed in as dust, or they may be transmitted directly from the sick to the well through personal contact, as in the use of drinking-cups or eating-utensils which have been employed by the sick, or through kissing the sick, or through the direct discharge of the secretions on the hands or face or clothing of the nurse or physician in attendance, in

making applications to the nose or throat of the sick person. Thus, in numerous ways the germs find their way from the throat of the sick to the mouth or air passages of the well, and if then the conditions are favorable for the development of diphtheria in the throat of the person receiving them, after a varying period the disease is produced. Diphtheria only follows the reception of the germs in the throat if favorable conditions for their growth exist there. In many cases the germs remain for many days and increase in number in the throats of healthy persons who have been in contact with cases of diphtheria, without producing the disease. Well persons who have these germs in their throats may convey them to others who contract the disease while they themselves escape. During convalescence from diphtheria the germs of this disease often persist in the throat for many days after all signs of disease in the throat have disappeared, and after the individual is entirely well. Investigations show that in about thirty per cent. of cases they persist for three weeks or longer after the beginning of the disease; in fifteen per cent. for four weeks or longer; in five per cent. for five weeks and occasionally even for a much longer time. Experiments have shown that almost invariably these germs are virulent and capable of inducing the disease in others, so long as they persist in the throat, and persons having such germs in their throats may convey the disease to well persons at any time. Observation, however, has proven that the chances of communication of the disease to well persons after complete convalescence are not great, excepting among children, who are far more susceptible to the disease and who are much more likely to become infected through the frequent introduction of articles into the mouth. The danger of communicating the disease to others after recovery is less than during the disease, because the number of germs is smaller and because the secretions are less abundant and not likely to be discharged so that they would be received by other persons. Where persons do not remain completely isolated, as they are strongly advised to do, until cultures made from the throat show the absence of the diphtheria bacilli, they should constantly remember the facts set forth in this circular and use every precaution to prevent the communication of the disease to other persons, and should be particularly careful in their relation and contact with children. Under no conditions will children whose throat secretions still show the presence of diphtheria bacilli be allowed to attend school of any kind, and under no conditions will adults be allowed to return to their occupation, where this involves immediate contact with children. [Signed] GEORGE B. FOWLER, M.D., *Commissioner of Health*. By order of the Board of Health. CHARLES G. WILSON, *President*; EMMONS CLARK, *Secretary*.

Fatigue.—The experiments of Masse, of Turin, and of Michael Foster, the physiologist, have shown that the sense of fatigue is due to poisoning of the cerebrum by the products of retrograde metamorphosis. "The blood of a tired animal is poisoned, and when injected into another animal causes the phenomena of fatigue." The toxicity of the blood may become so great as to prove fatal, as was shown by Foster, in rabbits that had been hunted to death.—*Dr. Bartour, in American Practitioner and News, January 25, 1896.*

The Doctor's Lien on the Baby.—An esteemed correspondent sends us the following: "The item in your issue of February 22d, in which the colored midwife of Gallatin, Tenn., wished to levy on the baby in order to secure the payment of her hard-earned fee, brings to

mind an incident which occurred in my own practice. I attended the wife of a young man in her first confinement, delivering her of a fine large boy. Several weeks after the father called at my office and asked for his bill, which being made out, receipted, and handed to him, he paid the money, remarking with evident satisfaction as he placed the receipt in his pocket: 'That boy belongs to me now.' It would be well for the profession if parents generally believed that the doctor had a lien on the child until the fee for the confinement is paid."

The Chemistry of Cleanliness.—The virtues of cleanliness are more than merely æsthetic. The sudoriferous glands perform the important function of throwing off the moisture produced during the combustion of waste tissue by the oxygen of the blood and secrete twenty-three ounces of perspiration in twenty-four hours. The conversion of perspiration into vapor renders latent a great amount of heat and keeps the body cool. Water at 120° F. is almost unbearable, but heat in an oven to the extent of 325° F. may be borne for a time. In the twenty-three ounces of perspiration secreted daily there is about one ounce of animal matter. This is left behind on evaporation. Sebaceous glands also secrete oily and resinous substances. This, mixing with the solid matter and dirt, forms a compound which tends to clog the pores of the skin. The removal of this compound is largely the source of the feeling of refreshment following a vigorous morning bath.—*Nature.*

The Simulation of Death by Indian Fakirs.—Dr. Kuhn has had occasion to observe two cases the genuineness of which he had no reason to doubt. One of the fakirs in question had been interred for six weeks and the other for ten days, says the *New York Medical Journal*. The fakirs, who are hysterical to the highest degree, possess the faculty of producing artificially a condition identical with cataleptic ecstasy. They use all possible means, such as mortification of the body by a special diet, the internal employment of different plants known only to themselves, and the adoption of a peculiar posture of the body for many hours, etc. When they have practised this for a sufficient length of time, they assume one of the postures prescribed by the sacred books of the Indians and fall into a hypnotic condition induced by looking fixedly at the end of the nose. Hasheesh is still made use of by them to diminish the respiratory force, for this hypnotic, when associated with other plants and employed in a peculiar manner, makes up for the loss of air and nourishment. The fakirs have hallucinations when hypnosis begins; they hear certain sounds, they see angels, and their faces express a feeling of happiness. But, little by little, consciousness disappears and the body acquires a peculiar rigidity. This is evidently, says the writer, a matter of self-hypnotism in hysterical persons who are sufficiently predisposed to it. This lethargy is looked upon by the people as death, and when the subjects are aroused it is God who has brought them to life. In Greek or Roman literature, says the writer, we may find accounts of persons who have died and returned again to earth. There is nothing astonishing in these facts, for Bouchut, in his treatise on the signs which enable us to recognize real death, reported the case of a woman who had been disinterred in order that a friend might look at her again. She was found to be alive, and she lived for many years afterward. Also in the Department of the North there was a case reported of a girl who had remained in a lethargic condition for several years. She had fallen into this condition on hearing that she was to be arrested for having committed a crime.

MILK AS AN AGENCY IN THE CONVEYANCE OF DISEASE.

By ROWLAND GODFREY FREEMAN, M.D.,
NEW YORK,

PATHOLOGIST TO THE FOUNDLING HOSPITAL; PATHOLOGIST TO ST. MARY'S FREE HOSPITAL FOR CHILDREN; ASSISTANT PHYSICIAN TO ROOSEVELT HOSPITAL, OUT-PATIENT DEPARTMENT.

DURING the past twenty-five years a large amount of evidence has accumulated about the causation of disease by milk, and many cases of illness and many epidemics caused by contaminated milk have been reported. It has thus seemed desirable to consider, as far as possible in a short paper, the conditions under which milk can become the means for the conveyance of infectious agents; to bring together and tabulate the recent epidemics of disease which have been attributed to milk, and, finally, to draw certain conclusions as to the methods which should be adopted to avoid such disease-producing contamination of milk.

Great Britain consumes² two hundred and fifty million gallons a year which costs £17,000,000 or \$85,000,000. The United States consumes³ five billion gallons a year. One may gain a more accurate conception of this latter amount by considering that it is nearly equal to the amount of Croton water consumed in New York City in one month. New York City consumes more than seven million gallons a year, an amount that would more than one-third fill the Bryant Park reservoir.

The Consumers of Milk.—Milk is consumed largely by infants and invalids, for many of whom it is the exclusive article of diet. It is, moreover, usually taken uncooked, either from indifference or on account of the altered taste of cooked milk. This particularly susceptible portion of the community is thus less protected than the robust adult people, who use for the most part food that has been more or less sterilized by cooking. The desirability then of great care in the handling of milk is evident.

Sources of Contamination of Milk.—Milk as it exists in the udder of a healthy cow is germ free, that is, it is practically sterile.

FIG. 1.—Petri plate exposed two minutes out of doors. Contains six colonies.

FIG. 2.—Petri plate exposed two minutes under cow being milked. Contains 1,800 colonies.

FIGS. 1, 2, and 3 show the extent of the contamination to which milk is exposed from the dust of the barn and the droppings from the belly and udder of the cow.

FIG. 3.—Petri plate exposed two minutes in barn. Contains 111 colonies.

I have collected and tabulated at the end of this article 53 epidemics of typhoid fever attributed to milk, 26 of scarlatina, 11 of diphtheria, 2 of foot-and-mouth disease, 3 of throat affection, 2 of acute poisoning by milk, and 1 of cholera asiatica. Only those occurring since 1880 are included, since a tabulation up to that date was prepared by Ernest Hart.¹

In inducing these diseases milk has served merely as the vehicle in which the micro-organisms producing the disease have been transported. In order to show clearly how the micro-organisms enter the milk, and why so much disease has been caused by milk, it may be well to look into the milk traffic and the methods employed in expressing the milk from the udder of the cow and the subsequent manipulation and delivery to the consumer.

Magnitude of the Milk Traffic.—The amount of milk produced, transported, and sold is very large.

But in fact milk as it comes to the consumer does contain a large number of living germs. These enter the milk in dirt, in dust, and in dirty water in various ways, and increase as rapidly as time and temperature allow. It is unfortunate that milk must be drawn from a hair-covered udder on the under surface of a hair-covered cow. This part of the cow's hide retains particles of any dirt on which the cow may lie, as well as dried faecal material, especially if the cow has loose evacuations. The droppings of dust and bacteria from the hide of cows during milking, even when the animals are kept fairly clean, are very great. The accompanying illustrations (Figs. 1, 2, and 3) are a practical demonstration of the extent of this contamination. Three Petri plates, three and one-half inches in diameter, containing a layer of sterile nutrient gelatin, were exposed for two minutes each on a gentleman's farm

near New York. One was exposed out of doors, a second in the barn, and a third under a cow just in front of the milk pail during milking. Subsequent examination showed that the plate exposed out of doors received six bacteria, while that exposed in the barn received one hundred and eleven bacteria, and that exposed under the cow received one thousand eight hundred bacteria. If one thousand eight hundred bacteria will fall from the belly of a cow during milking in a circle three and one-half inches in diameter in two minutes, one can easily appreciate the immense number that will fall into an ordinary milk pail during the whole period of milking. This, however, is only one of the sources of contamination. The milkman, wearing clothes from which much dust falls, leans forward over the pail, his arms especially being shaken over the pail. The friction between the milkman's hands and the teats of the cow causes the removal of the dirt and epithelium from both the hands of the milkman and the teats of the cow. This friction is often lessened by what is known as wet milking. When this is practised, a stream of milk from the teat is directed against the palms of the milkman's hands, first one hand and then the other, the hands being then applied to the teats. The result is that the teats of the cow and the palms of the hand of the milkman are practically washed over the milk pail and drops of milk expressed from between the hand and the teat fall into the pail below. A less important but still material source of contamination is the dust of the barn. In the illustrations to which I have already called attention (Figs. 1 and 3) it is seen that while only six bacteria fell into the plate out of doors, one hundred and eleven fell during the same time in the barn.

Contamination of milk by impure water is of frequent occurrence. Such water is often used in washing the pails, or it may be introduced into the milk by submersion of the milk in pails or cans in contaminated water for cooling. Or adulteration of milk with dirty water may occur. The quality of the water used in many dairies has apparently received little attention.

It is thus seen that during and immediately after milking, an extensive contamination of the milk takes place, and by no practicable method yet adopted has it been possible to entirely prevent it. Fresh milk appears to have some germicidal action. The writer has found a constant diminution in the number of bacteria in certain specimens of milk during the first twelve hours after milking. Fokker¹ has reported similar results, noting a diminution in the number of bacteria during the twenty-four hours after milking. Such germicidal action of milk, however, cannot be depended on, for milk will sometimes sour within twenty-four hours after milking. It is, therefore, desirable that milk should be kept cold and consumed or sterilized within twenty-four hours after milking. The influence of temperature on the growth of bacteria in milk was well shown by the following experiment: From a specimen of milk a certain amount was put in four sterilized test tubes. These samples were left for twenty-four hours at different temperatures. At the end of twenty-four hours a fixed amount from each sample was planted in a plate and the number of colonies that developed in each plate was counted. A photograph of the plates at the time the counts were made is shown (Figs. 4, 5, 6, 7). The one kept at 7° C. (45° F.) had 445 colonies; that at 10° C. (50° F.) 1,362 colonies; that at 13° C. (55° F.) 67,170 colonies; while the one at 20° C. (68° F.) showed 134,340 colonies. Such experiments show that milk should be kept at a temperature below 10° C. (50° F.) until sterilized or consumed. It has been stated already that milk should not be kept raw for

more than twenty-four hours. New York milk, even that of the better sort which is brought to town in bottles and sold at eight or ten cents a quart, is usually thirty-six or forty-eight hours old when delivered to the consumer. Some milk shipped to New York from a distance of over three hundred miles is actually nearly twenty-four hours old when shipped. The transportation of milk is by milk trains, which are very slow, often making only seventeen miles an hour.

A consideration of the foregoing statement prepares one for the results of the examination of ordinary New York milk, which often contains from a hundred thousand to several million bacteria in each drop. Our present dairy methods allow ample opportunity for the entrance of bacteria, either non-pathogenic or even pathogenic, should the latter sort be present. The long interval between milking the cow and delivering the milk to the consumer allows ample opportunity for the bacteria to multiply.

Disease Conveyed by Milk.—The diseases which, it is believed, may be conveyed by milk are conveniently divided into three classes:

I. Those in which the pathogenic micro-organisms which are introduced into the milk are conveyed from the body of the diseased cow, as tuberculosis, anthrax, foot-and-mouth disease, and acute enteritis.

II. Those in which the pathogenic micro-organisms are introduced into the milk from some other source either during or after milking, as cholera, typhoid fever, scarlet fever, and diphtheria.

III. Those caused by milk which contains poisonous agents developed by bacterial growth.

I. Diseases Conveyed by Milk from a Diseased Cow.—Contamination of milk with disease germs which emanate from the cow may occur while the milk is still in the udder, in the case of certain general diseases and especially in diseases of the udder, or the contamination may take place during milking by the dropping of particles of faecal matter from the cow or from the dust of the barn, which may contain dried particles of faecal material or saliva of the cow.

Liability to Faecal Contamination of Milk During Milking.—Most cases of contamination of milk with disease germs originating from the cow have been attributed to milk infection in the udder; on the other hand it is evident that contamination is very liable to occur from dried particles of faecal matter dropping into the pail, especially when the animal is having loose evacuations. Socrates, as quoted by Xenophon in his "Memorabilia," discourses on the wisdom of the gods in placing our eyes, nose, and mouth in the position which they occupy, and "since what passes off from the stomach is offensive, to turn the channels of it away and remove them as far as possible from the senses." Had the wise Socrates pursued his observations in a dairy, I fear he would have been inclined to criticise the judgment of these deities in the case of the cow in turning her channels loose just above the udder, thus not only endangering the sucking calf, but making the inevitable position of the milk pail one of considerable hazard. Watery evacuations from a cow pass naturally along its thighs and on to the posterior portion of the udder. It is not unusual in a dairy to see an udder that is soiled by faecal matter with large dried masses hanging by its hair, and these are shaken over the pail during milking.

Tuberculosis in Cattle.—Tuberculosis is probably the most important of those diseases whose germs are liable to be conveyed by milk and in which the contamination of the milk may arise from the cow. It is a very prevalent disease, existing to the greatest extent in the neighborhood of large cities. Estimates as to the proportion of cattle that are tuberculous in

different sections of this country and abroad vary widely. Those estimates which are based simply on the opinions of veterinarians from physical examination alone should be rejected as unreliable. Slaughter-house statistics furnish definite information, although some cases with but slight tuberculous disease undoubtedly pass unrecorded.

In the following table is given the percentage of cattle reported tuberculous in the slaughter houses of certain cities and countries:

Berlin ⁵	4.57%
Munich ⁵	2.44%
Augsburg ⁵	2.24%
Mulhausen ⁵	3.4%
Hanover ⁶	60-70%
France ⁶	5%
Paris ⁶	6%
Holland ⁶	20%
Pomerania ⁶	50%
Mexico ⁷	34%

The use of tuberculin followed by autopsy in cases where a significant reaction is obtained gives a basis of statis-

but no evident involvement of the udder. By a very thorough examination of stained specimens of milk of thirty-six such cows, the bacillus tuberculosis was found in twelve or thirty-three per cent. Moreover, it should be remembered that milk from a cow with general tuberculosis which is free from tubercle bacilli when it leaves the udder of the cow may become contaminated during milking. Should such a cow have a tuberculous enteritis and pass tubercle bacilli

in its feces, its milk is very liable to become contaminated by the dropping of dried particles of fecal material from the posterior portion of the udder during milking.

Action of Gastric Juice on the Bacillus Tuberculosis.—Considering the immense amount of milk used, the large amount of tuberculosis among cattle, and the fact that cows with no lesion of the udder may produce milk containing tuber-

FIG. 4.—445 colonies, 24 h. at 7° C. (45° F.).

FIGS. 4, 5, 6, and 7 show the effect of different temperatures on the growth of bacteria in milk.

FIG. 5.—1,362 colonies, 24 h. at 10° C. (50° F.).

tics which should indicate a larger percentage of tuberculous animals than any other, for tuberculin will give a reaction where lesions exist that are so small that they might easily be overlooked in any ordinary physical examination or even autopsy.

Statistics derived from the use of tuberculin will never be quite satisfactory so long as herds are examined with tuberculin only when the owner requests such an examination. In Massachusetts⁸ more than one-fourth of the cattle in herds examined by request are found to be tuberculous, the percentage of tuberculous cows in a herd varying from 0.9 to 95 per cent. In New York State⁹ the use of the tuberculin test has made it seem probable that nearly seven per cent. of all the cattle of the State are tuberculous.

A consideration of these statistics leads one to inquire whether all tuberculous cows produce milk containing the bacillus tuberculosis. Do tubercle bacilli appear in the milk only when there is disease of the udder, or may they be present when the cow has general tuberculosis but no lesion of the udder? Bang⁹ found that of sixty-three cows having general tuberculosis, but no nodules in the udder, nine gave milk containing the bacillus tuberculosis. Ernst¹⁰ found the bacillus tuberculosis present in a much larger proportion of cows having general tuberculosis,

FIG. 7.—134,340 colonies, 24 h. at 20° C. (60° F.).

cle bacilli, one may be surprised that milk does not produce more tuberculosis in men. A certain amount of protection is provided by the mixing of milk in large cans, thus, so to speak, diluting the virus.

Gebhardt¹¹ found that milk of tuberculous cows which was virulent when pure lost its virulence when diluted, in some cases forty times, in others fifty or one hundred times.

Cooking and sterilizing milk also renders a considerable amount innocuous.

It has been thought that a protection may be provided by a germicidal action of the gastric juice on the tubercle bacilli. That such protection is not afforded by the gastric juice of guinea-pigs has been shown by experiments of Baumgarten¹² and of Fischer,¹³ nor by artificially prepared gastric juice by those of Falk.¹⁴ In fact, primary intestinal tuberculosis in man does occur. Dr. Sims Woodhead¹⁵ states that he has seen a very large number of cases in which infection seemed to be from the intestine. Cohnheim, Aufrecht, and Peterson¹⁶ hold the same view. Three cases of evident primary tuberculosis of the intestine have been reported in this city recently: one in an adult by Dr. Hodenpyl¹⁷ and cases in infants by Dr. Northrup,¹⁸ and by Dr. J. Lewis Smith, and the writer.¹⁹

Clinical Evidence of the Transmission of Tuberculosis by Milk.—Clinical evidence of the transmis-

sion of tuberculosis by milk is less satisfactory than that furnished by some other diseases on account of the less acute character of this disease and the varying degree of susceptibility to it in different individuals. Some cases, however, are reported in which the evidence against the milk is fairly strong. Thus, in a dairy in England²⁰ three cows were found to have tuberculous disease of the udder. In the institution to which this milk was supplied the mortality from tuberculosis during the last year was thirty per cent. and during the preceding year forty per cent. of the total mortality. Brouardel²¹ reported that in a boarding-school in which there were fourteen girls five contracted tuberculosis from drinking the milk of a tuberculous cow. Ollivier²² tells of another boarding-school in which milk from a tuberculous cow was used and in which thirteen cases of tuberculosis occurred. Dr. Demme²³ states that in the Child's Hospital at Berne four infants, with no tuberculous ancestry, died of intestinal and mesenteric tuberculosis as the result of feeding on the unsterilized milk of a tuberculous cow. Many cases have been reported in which, from among a number of persons using the milk of a single cow, one child has died of tuberculosis. There has been no tuberculous family history and no known contact with any tuberculous person. The only apparent source of infection has been the milk. The cow from which the milk was obtained has been examined and found tuberculous. Such cases the writer has thought best not to include in this paper, as the evidence seemed insufficient although significant.

It may be considered an established fact that tuberculosis may be induced in man by drinking raw milk from a cow suffering from tuberculosis.

Anthrax.—Concerning anthrax there is some evidence that it is communicated by milk, although it is not altogether satisfactory. The anthrax bacillus has been found in the milk of animals suffering from anthrax by Nocard²⁴ and others. The clinical evidence seems to rest largely with Heusinger,²⁵ who wrote in 1850, and in whose statements German writers place considerable confidence. Heusinger said that it was proved that milk and butter from animals suffering from anthrax possess virulent properties by numerous observations in America and Russia, and that the malady produced was the milk sickness of America. Heusinger was evidently in error in his opinion that anthrax and milk sickness are identical. Milk sickness certainly differs in symptoms and prognosis from intestinal anthrax. I have found no American writer who associates the two diseases.

Foot-and-Mouth Disease.—That foot-and-mouth disease may be communicated by milk has been demonstrated experimentally. Hertwig²⁶ and two friends drank daily for four days a quart of milk each from a cow suffering from foot-and-mouth disease. In less than two days the symptoms of the disease appeared in each and lasted five days. The mucous membrane of the mouth became swollen and on that covering the inner surface of the cheek small vesicles appeared. Vesicles appeared also on the hands in one case. The results of Hertwig were confirmed by Jacob.

In 1884 an epidemic²⁷ occurred in Dover, England, which involved one hundred and thirty consumers of the milk of one milkman. The attacks were characterized by shivering followed by headache, fever, pain in limbs, thirst, parched lips, and a vesicular eruption of the throat. On one of the farms supplying this milkman the cows were found to have been suffering from foot-and-mouth disease. Other cases of foot-and-mouth disease transmitted to man by milk are reported by Weigel and Noack,²⁸ Schäffer and Esser,²⁹ Esser and Schütz,³⁰ and Weissenberg.³¹ In this country foot-and-mouth disease is comparatively unknown.

Acute Enteritis.—Another disease which has been demonstrated to have been caused by milk infected by the cow is acute enteritis. The following case reported by Gaffky³² is particularly interesting, since the milk in the cow's udder contained no bacteria, the bacteria being introduced into the milk probably during milking from the dried particles of fecal matter on the posterior portion of the udder, which, during milking, fell into the pail. This case presents so much good evidence that I will briefly review it. On October 10, 1891, three men connected with the Hygienic Institute at Giessen were suddenly taken sick; they were the assistant, the chemist, and the janitor.

They had chills, fever, diarrhœa, and constitutional symptoms. The assistant was very sick for two weeks, his temperature reached 106° F., he was delirious, passed blood with his stools, and had albuminuria. The chemist had the same sort of illness, but less severely, his temperature never rising above 104.7° F. The janitor again had the same type of illness but still less severely, with a temperature never above 104° F. On investigation it was found that the only article of diet of which they had all partaken was milk. The assistant had a litre of milk in the laboratory the previous day, of which he had taken more than half for his breakfast; the chemist had taken one cup, while the janitor had less than that, finishing what was left. This milk was traced to a cow that was suffering from hemorrhagic enteritis and passing watery feces containing blood clots. The milk of this cow as it left the udder contained no germs. In the feces a short active bacillus was found, which proved very pathogenic for mice and guinea-pigs, and which corresponded to what had already been found in the stools of the patients. Here, then, we have a clear case of fecal contamination of the milk from the cow.

In Manchester, England, in November, 1894, an epidemic occurred³³ characterized by diarrhœa, sickness, and abdominal pain. There were one hundred and sixty cases in forty-seven houses, all served by the same milkman, they being fifty per cent. of all the houses he served. This was referred to a case of garget in a cow at the dairy.

II. Diseases Conveyed from One Human Being to Another by Milk.—Passing now to those diseases in which milk appears to be a carrier of infectious material through contamination by some person suffering from one of these diseases, we must first note that evidence of such contamination has not been demonstrated bacteriologically. Although typhoid fever, cholera, diphtheria, and scarlet-fever epidemics have been attributed to milk, in no case, so far as I know, has it been possible to demonstrate the particular organism in the specimen obtained. The organism of scarlet fever is not known, but those of typhoid fever, cholera, and diphtheria are familiar to bacteriologists. From this negative bacteriological evidence some writers are disinclined to accept the evidence we have as conclusive.

Characteristics of Epidemics Due to Milk.—There are certain characteristics of epidemics due to milk, whether they be epidemics of typhoid fever, scarlatina, diphtheria, or gastro-enteritis, which it may be well to point out.

1. The cases appear suddenly, many new cases each day, and the subsidence is equally marked a few days after stopping the harmful milk supply.

2. The houses invaded are often widely distributed and not restricted to some particular part of the town.

3. The houses of the rich are apt to be more seriously invaded than those of the poor, because poor people as a rule use very little milk. The houses invaded often have the best hygienic surroundings and frequently they have a different water supply and

a different sewage system from others in which the disease exists, so that these possible causes of the epidemic may be eliminated. In the Yorktown and Camberly epidemic of diphtheria due to milk in 1887, while eighty-four per cent. of the houses of the better class using the milk were invaded, only twenty-two per cent. of the poorer class using the milk were invaded, and while thirty-three per cent. of the consumers of the better class acquired diphtheria, only six per cent. of those of the poorer class acquired it.

4. The special milk drinkers in each family are most liable to become affected. Thus in the epidemic I have quoted seventy-eight per cent. of the special milk drinkers were affected, while only twenty-seven per cent. of those not special milk drinkers were affected. Those who take but little of the infected milk are not, however, exempt from the disease. In a recent epidemic of typhoid fever caused by milk, one gentleman who carefully procured his milk from an excellent dairy inadvertently purchased ice cream without inquiring the source of the milk from which it was made. The ice cream had been made from the milk of the infected dairy; the result was the death of one child from typhoid and the illness of all the other members of the family, including the father, mother, and one other child.

5. Children are most liable to be affected. In the Stamford epidemic of typhoid fever out of three hundred and eighty-six cases one hundred and thirty-four, or 34.8 per cent., were children, although the greatest liability to typhoid exists between the ages of twenty and thirty. In the Yorktown and Camberly epidemic of diphtheria, while only 17.6 per cent. of the adult drinkers of the milk were affected, 30.2 per cent. of the children suffered.

6. In the epidemics those affected are found to be for the most part the drinkers of a certain milk supply—in Stamford, 376 of a total of 386; in Springfield, Mass., 135 of 150; in Somerville, Mass., 30 of 35; in Manchester, England, 107 of 115. In some other epidemics, as may be seen by the tables near the end of this article, all the cases were among drinkers of the contaminated milk. When it is found that the same milkman does not supply most of the houses invaded, it is sometimes found that several milkmen obtain their supply from one dairy and that in this dairy the infection has taken place. In other epidemics but a small proportion of the suspected milkman's route is invaded, as in Springfield, and this is on investigation explained by the fact that the milkman obtained but a small proportion of his milk from the farm where the infection took place.

7. In more than half of these epidemics due to milk cases of the disease preceding the epidemic have been found among the milk handlers. When such cases have not been found, it is usually not possible to say that they have not existed.

Typhoid Fever.—In the case of typhoid fever we have a large amount of evidence which, while it is circumstantial, is at the same time very conclusive. Although the *Bacillus typhosus* has not been found in any of the specimens examined, it does not follow that it was not present at the time the epidemic was started. The organism of typhoid fever thrives in milk. It does not seem possible that any one who has studied the recent literature concerning epidemics of typhoid fever due to milk could doubt the causative relation of the contaminated milk. Very many outbreaks of this sort have been inadequately reported without exact statistics and some have never been reported at all. We have, however, a sufficient number which have been capably investigated and accurately reported to furnish conclusive evidence. Ernest Hart collected fifty outbreaks of typhoid due to milk

previous to 1881. I have collected fifty-three occurring between 1881 and 1895, which are tabulated near the end of this article. In all these the evidence was fair, while in certain of them it seems to me absolutely conclusive, as in the recent Stamford epidemic, in which the distribution of cases followed almost exactly the milk route of the offending milkman; or that at Bay Head, where fifteen out of the sixteen cases were among the drinkers of the milk from a dairy where an employee had suffered from typhoid; or that at Montclair, N. J., where one hundred and thirty-five out of a total of one hundred and fifty cases were among drinkers of milk from a filthy dairy, the owner of which had himself suffered from typhoid just previous to the epidemic. Compare these statistics with those of epidemics due to polluted water. In the Lowell and Lawrence, Mass., epidemic of 1891,³⁴ for instance, of four hundred and eighty cases only fifty were supplied by one milkman, while the cases occurred among the customers of one hundred and thirty-five milkmen. Of the fifty-three outbreaks of typhoid fever which I have collected and tabulated, ten occurred in this country and thirty-one in Great Britain. These epidemics were distributed pretty equally during the year. I note the months in which thirty-three of these epidemics occurred, some, of course, running through several months, as follows: January, 4; February, 4; March, 6; April, 4; May, 5; June, 5; July, 6; August, 10; September, 4; October, 3; November, 4; December, 4. The greatest number (ten) occurred in August, while the smallest number (three) occurred in October. Of fifty-one epidemics,³⁵ in thirty-three a case of probable or positive typhoid was found, which was believed to have caused the contamination of the milk. In six the water used was polluted (and one of these was found to contain the *Bacillus coli communis*), while in two the premises were found in bad condition. In thirty-one epidemics a case of typhoid was found to have occurred in the house of the farmer or milkman preceding the epidemic. The means of transmission of the typhoid germs in these epidemics was simple. In some cases the typhoid existed in a mild form, so that the patient actually worked in the dairy. Often the same person nursed the patient and worked about the dairy, sometimes milking the cows. The dairy pails were often washed in the kitchen, which in one case opened into the sick-room, and the same towel may be used for the patient and for drying and cleaning the pails, or the privy may be found close to the dairy well, no disinfection of faces having taken place. In one place (Springfield) the contents of the privy in which the stools of a typhoid patient were deposited were spread over a field through which the farm laborers walked, thus affording opportunity for infecting their shoes. The milk was cooled by submerging it in a well covered by boards on which lay lumps of manure. Before being submerged the milk cans were stoppered by wooden plugs. There was some leakage around these plugs in four of nine cans tested, so that the water from the well entered the cans. The water of this well was found to contain the *Bacillus coli communis*, thus giving evidence of faecal contamination. In some epidemics, in which the disease has occurred mostly among the consumers of one milk supply, no typhoid fever has been found either at the dairy or in the family of the milkman. Among these there has been found, in different cases, a sewage field near the dairy, a tank of filthy water at the dairy, a sewer trap within a foot of the well. It does not of course follow that because no evidence of infection of milk by a person can be secured that therefore such infection did not take place. In the investigation of epidemics it has always been most difficult to secure the facts, since those who pos-

sess them are very unwilling to communicate them, fearing injury to their business.

A new danger due to modern methods of handling milk is the creamery. It is the custom at creameries to receive from the farmers in the neighborhood milk which is mixed in the separator, and after separation the skim milk is returned to the farmers in the proportion in which it was contributed. In three recent epidemics (Svarteborg, 1889, one reported by Welpey, 1893, and that at Castle-Island, Ireland, in 1894) the disease appeared first in one of the contributing farms and spread through the contamination of the milk at the creamery to the other contributors. In the epidemic reported by Welpey all the twenty-three cases occurred among contributors to the creamery. Attention having been called to this danger, the authorities in some places have taken steps to control it. In a recent number of the *British Medical Journal* it was stated that during a serious outbreak of typhoid fever at Castle-Island, Ireland, the proprietor of a creamery was fined £5 for accepting milk from farms on which typhoid fever existed.

Scarlatina.—In studying the relationship of scarlatina to the milk supply, we find some very conclusive evidence that certain epidemics of this disease have been caused by contaminated milk. In about the same proportion of the cases, however, as in typhoid fever do we find evidence of the contamination of the milk by a person suffering from scarlatina. Thus, of twenty-six recent epidemics, all occurring in England, in fifteen cases there was evidence of contamination from a case of the disease in man. The lack of such evidence in some cases has directed attention to the condition of the cows furnishing the milk, although it may be accounted for by the high degree of contagiousness of the disease and the fact that very mild cases occur which can never be recognized except as they occur with others. A series of publications by Klein attribute some of these epidemics to slight lesions about the udder and teats of the cows producing the milk which caused the sickness. Klein's work, however, has never been confirmed. It seems to me a humiliating fact that not one epidemic of scarlet fever due to contaminated milk, so far as I have found, has been reported in this country. This is not in all probability because they do not occur, but for the reason we all know to exist, because the source of milk supply is not ordinarily inquired into. It should certainly be the duty of all inspectors of boards of health to ascertain the milk supply of each family in which any case of contagious disease occurs.

Diphtheria.—Some epidemics of diphtheria have been found to exist almost solely among the consumers of a certain milk supply. Diphtheria epidemics traced to milk are, however, less common than those of scarlet fever. In only five of eleven epidemics of diphtheria traced to milk that I have tabulated was any diphtheria found at the dairy. Of the seven epidemics reported by Hart, in only one did he find diphtheria at the house of the milk dealer. In certain of these epidemics the cows have been suspected of being the cause on account of a contagious eruption on the teats or a ropy consistency or unpleasant taste of the milk. These observations concerning the animals are strongly opposed by many authorities, and should not be considered until more evidence is produced, for many light cases of true diphtheria exist which do not produce severe constitutional symptoms. It is not altogether improbable that all these epidemics may have been caused by diphtheria in man, and that either the man was unaware that he had the disease or that its existence was not known to the authorities. The *Bacillus diphtheriæ* grows well in milk. Of thirteen epidemics of diphtheria attrib-

uted to milk contamination, one occurred in January, none in February or March, one in April, two in May, four in June, four in July, three in August, none in September, three in October, two in November, and four in December, while in two the month in which they occurred is not stated. All but two of them occurred in Great Britain and one was reported in this country. One of these epidemics, that at Yorktown and Camberly, reported by Power, presents so many instructive features that it seems worth while to point to some of them as illustrating certain characteristics of epidemics due to milk. One hundred and forty persons in fifty-seven households were taken sick in October and ninety per cent. of these during an interval of ten days between October 8th and 18th. Of the fifty-seven households affected, forty-eight, or 84.2 per cent., had the suspected milk, and of the one hundred and forty persons one hundred and twenty-four, or 88.5 per cent., drank the suspected milk. Rich people were attacked in larger proportion than the poor, and this fact would seem to be accounted for by the fact that rich people consumed an average of over five pints a day, while poor families averaged less than a pint each. While eighty-four per cent. of the families of the better class were affected, only twenty-two per cent. of the families of the poorer class were affected. Thirty-three per cent. of consumers of the better class were affected and only six per cent. of those of the poorer class. In these statistics also we have an example of the greater liability of children on account of the amount of milk they consume, for while twenty-nine per cent. of the adults of the better class were affected, fifty-four per cent. of the children of the better class were affected. These statistics also show the greater susceptibility of special milk drinkers, for, while only twenty-seven per cent. of the consumers who were not special milk drinkers were attacked, seventy-eight per cent. of the special milk drinkers were attacked. And again, among children ten per cent. of those not special milk drinkers were attacked, while seventy per cent. of the special milk drinkers sickened. It was also found that cream drinkers were not more affected than those using milk. A valuable lesson is taught in the fact, that on account of the larger amount of milk consumed, it is much easier to trace such an epidemic to its source by investigations among the well-to-do than among the poor.

Cholera Asiatica.—That cholera may be spread by milk we have good reason to believe. The bacillus of cholera grows well in milk when it has been previously sterilized. It is, however, considered that its growth in milk may be retarded by the presence of many other bacteria. Basenau³⁶ has found cholera bacilli active in raw milk thirty-two hours after their introduction in several experiments at different temperatures. Gaffky,³⁷ who has written on cholera in India and Egypt and is considered a reliable observer, says that milk is not infrequently a means of communicating cholera. An epidemic of cholera on ship-board reported by Simpson³⁸ furnishes conclusive evidence of infection through milk. Of the ten sailors who drank the milk, all had cholera, while of the remaining fourteen members of the crew only one had cholera. The milk was furnished by a man who did washing for the crew. He afterward acknowledged that he mixed the milk with one-fourth part of water from a tank. The water from this tank was found to have caused an epidemic of cholera in the neighborhood.

III. Diseases Caused by Milk which Contains Poisonous Agents Developed by Bacterial Growth.—Cases of poisoning by milk and milk products have been reported. A serious case of milk poisoning supposed to have been caused by a ptomaine occurred at

TABLE SHOWING TYPHOID-FEVER EPIDEMICS DUE TO MILK CONTAMINATION.

Date	Town.	Reported by	Reference.	Total Number of Cases.	Cases among Consumers of the Infected Milk.	Deaths.	Was Typhoid Found among the Milk Handlers?	Remarks.
Aug., 1881	Hawick		Br. Md. Jr., '81, ii., 273			..	Yes.	Nearly every case received milk from a farm where typhoid prevailed. Milk supply stopped.
1881	Christ Church, New Zealand.		Br. Md. Jr., '81, ii., 570			..	No.	All houses infected (including a lunatic asylum) were supplied by same dairy. Dairy premises in a filthy condition.
1882	Glasgow.....		Br. Md. Jr., '82, ii., 500.			..	Yes.	Cases were consumers of milk from a dairy where typhoid had recently existed.
Nov., 1882	Grangemont		Br. Md. Jr., '82, ii., 911			..	Yes.	Cases supplied with milk from a house where there was a case of typhoid. Milk was ordered destroyed until the typhoid patient was removed.
Aug. and Sept., 1882	Stonechair.....	Bridson.....	Br. Md. Jr., '82, ii., 749.	11	11	1	Yes.	Two suspicious illnesses at dairy, which had preceded epidemic and were thought to be typhoid.
July., 1882	Clapham	Parsons.....	Br. Md. Jr., '82, ii., 216.	20	19	..	No.	All attacked within twenty-four hours of each other. Spread of disease stopped within a few days of stoppage of milk supply.
May, 1882	Glasgow.....	Russell.....	Br. Md. Jr., '82, ii., 61	59	50	2	No.	Nearly all taken sick within a week.
Jan. to July, 1883	Cologne.....	Auerbach.....	Schmidt's Jahrb., '83, ccvii., 72.	280	61	..	Yes.	Several cases of typhoid at dairy. One case nursed near cow stable.
1883	Warwickshire	Wilson.....	Br. Md. Jr., '83, i., 1,136.	12	12	1	Yes.	Milk dealer died from typhoid and his son contracted it from him. Milkman's water supply polluted.
1883	Dundee		Br. Md. Jr., '83, ii., 839.	102	36	..	Yes.	Several members of dairyman's family were suffering from typhoid.
Feb., 1883	Gateshead.....	Green.....	Lancet, '83, ii., 986.			..	No.	Several cases. All but one received milk from one dairy. Premises in bad condition.
Aug., 1883	St. Pancreas.....	Murphy.....	Lancet, '83, ii., 652.	431	368	62	Yes.	Of twenty employees of milkman, eight contracted typhoid.
1883	Upsala	Almqvist.....	Ztschr. für Hyg., vol. 80, p. 137.	37		..	Yes.	Followed typhoid in milkman's family.
Oct. to Dec., 1883	Port Jervis.....	Curtis.....	Rep. N. Y. Bd. of Health, '84, 185.	149	128	..	Yes.	Typhoid at dairy in August and September, three cases. These were nursed by the same person who attended to the dairy work.
Dec., 1884	Aberdeen.....	Simpson.....	Br. Md. Jr., '84, i., 103.	65	43	7	No.	The first five cases occurred near the dairy. Probably due to polluted dairy water.
Dec. to March, 1885	Groningen.....	Ali Cohen.....	Schmidt's Jahrb., cxxx., 197.	58	43	..	No.	
1886	Shoreham	Kelly.....	Practitioner, '86, xxxvii., 223	80-100	80-100	..	No.	Traced to one dairy. Probably pollution from water.
March to May, 1887	Carlisle.....	Brown.....	Practitioner, '88, ii., 413.	25	23 or 24	..	No.	Febrile disorder among the cows at the dairy early in March.
.....	Minnegue	Janssen.....	Rouvier, le Lait, p. 268.			..	Yes.	All the cases had milk from one dairy. In one family all who drank the milk raw contracted typhoid, while those who drank it cooked escaped. Water supply near privy. Case of typhoid previously in farmer's family. Epidemic stopped with withdrawal of milk.
July to Aug., 1888	Providence.....	Swarts.....	Not published.	90	86	..	Yes.	Three cases of typhoid at dairy. One a few weeks preceding epidemic.
1888	Durham.....	O'Hanlon.....	Lancet, '88, ii., 941.	12	12	..	No.	Traced to one milk route. Typhoid fever found at one of the farms supplying this milk route.
Nov. 1888	Cambridge, Mass.	Harrington.....	Rep. Mass. Bd. of Health, '88, p. 25.	73	58	..	Yes.	
March, 1889	Melbourne.....	Allen.....	Intercol. Med. Congress, Melbourne, '89.	43	43	..	Yes.	Originated in a case in the family of the milk dealer.
1889	Sterling	McFadyen.....	Br. Md. Jr., '89, i., 1,250.	40 or 50	40 or 50	4	Yes.	Several cases at the dairy preceding the epidemic.
1889	Leeds	Goldie.....	Br. Md. Jr., '89, ii., 110	20	20	..	No.	Originated from milk supply.
July and Aug., 1889	Belgrade	Roth.....	Schmidt's Jahrb., vol. cxxxviii., 204.	10	10	..	Yes.	Son and grandson of woman who kept a milk store had typhoid preceding the outbreak of typhoid, which was confined to drinkers of this milk.
June to Sept., 1889	Svarteberg.....	Almqvist.....	Ztschr. für Hyg., '90, viii., 137.	104		11	Yes.	Epidemic originated in a creamery. Typhoid occurred in one of the contributing farms, contaminated its milk, and thus all the milk was infected.
June, 1890	Waterbury	Smith.....	Conn. Bd. of Health Rep.	50	41	..	Yes.	Three cases of typhoid in the milkman's family in May and June.
1890	Geneva, Switzerland..	Vincent.....	Lancet, '90, ii., 730; Br. Md. Jr., '92, i., 1,279.			..	No.	Traced to the milk of one dairy. It was shown that the dairyman washed his pails in a stream in which the linen of a typhoid patient was washed. Milkman sued dairyman for damages and got 1,500 francs.
1891	Whitechurch		Br. Md. Jr., '91, ii., 1179.			..	Yes.	Cases occurred among drinkers of milk from a dairy where a child sick from typhoid was allowed to handle dairy utensils. Milk dealer fined.
Feb. to April, 1891	Sutton-Coldfield.....	Hill.....	Br. Md. Jr., '91, p. 130	40	40	5	No.	All cases had contaminated milk. Epidemic stopped by stopping milk supply.
Sept. to Nov., 1891	Edinburgh	Littlejohn.....	Edinb. Med. Jr., cxxxix., '91	63	63	..	Yes.	Child sick with typhoid at the dairy.
Aug., 1891	Showland near Glasgow, Scotland.	Monro.....	Public Health, iv., p. 275.	42	37	6	Yes.	A probable case of typhoid at dairy from June 13th to August 10th.
Aug. and Sept., 1892	Dundee	Anderson.....	Br. Md. Jr., '92, ii., 902	82	43	6	Yes.	Typhoid at dairy in August. Milk supply stopped August 28th.
June, 1892	Nottingham	Poobyer.....	Public Health, '92, iv., 110	7	7	..	Yes.	Dairy assistant worked for three weeks while suffering from fever, vomiting, and diarrhoea. Dairy supplied twenty-six families.
Dec., 1891, to Jan., 1892	Clermont-Ferrand..	Gayon, etc.....	Rev. de H., '92, 993.	23	18	6	Yes.	Originated in dairy where the proprietor and his daughter had typhoid.
1892	Near Leeds.....	Ballard-Arnsley.....	Stevenson and Murphy, Hygiene, i., 334.			..	No.	Every case except one supplied by milk which had been mixed with contaminated water.
1892	Plymouth	Williams.....	Br. Md. Jr., '92, i., 1,157	12		1	No.	The one fatal case was that of a young man on a milk diet.
Aug., 1892	Springfield, Mass.....	Sedgwick.....	Bost. Md. and Surg. Jr., '93, ii., 489.	150	135	25	No.	Bacillus coli communis found in dairy-well water. Milk cans cooled by submerging in well after plugging with wooden plugs which leaked.
1892	Somerville, Mass.....	Sedgwick.....	Bost. Md. and Surg. Jr., '93, ii., 489.	35	31	..	Yes.	Son of dairyman had typhoid and worked in the dairy during the early part of the epidemic.
Aug., 1893		Welpey.....	Lancet, '94, i., 592	23	23	..	Yes.	Creamery case. Typhoid on one of the farms contributing to the creamery. Nineteen cases infected from the creamery milk.

TABLE SHOWING TYPHOID-FEVER EPIDEMICS DUE TO MILK CONTAMINATION—Continued.

Date.	Town.	Reported by	Reference.	Total Number of Cases.	Cases among Drinkers of the Infected Milk.	Deaths.	Was Typhoid Found among the Milk Handlers?	Remarks.
1891	E. near Strasburg.	Schmidt.....	Hyg. Rundsch., '94, p. 694			..	No.	All the cases had milk from one milkman. Seventeen per cent. of those who drank the milk had typhoid, while among three hundred others there was no case. Epidemic stopped on withdrawal of milk.
1894	Castle-Island, Ireland.		Br. Md. Jr., '94, i., 815			..	Yes.	Creamery case. Local creamery had received milk from a family in which typhoid existed.
March, 1893	Montclair	Hunt.....	Rep. N. J. Bd. of Health, '94, 35.	115	107	15	Yes.	Son of milkman had typhoid just preceding epidemic.
July, 1894	Bay Head	Hunt.....	Rep. N. J. Bd. of Health, '94, 41	16	15	..	Yes.	Case in an employee of dairy preceding epidemic.
1894	Brixton	Verdon.....	Br. Md. Jr., '94, i., 1,112	60		10	No.	Polluted water at dairy.
1894	South Lambeth.....	Verdon.....	Br. Md. Jr., '94, i., 1,149	59	55	10	No.	Polluted water at dairy.
Oct., 1895	Shettleston.....	Wilson.....	Br. Md. Jr., '95, iii., 1,204	35	15	2	Yes.	Case of typhoid at dairy in September. Dairy supplied sixteen families and seven of these, or over forty per cent., suffered.
		Tripe, ...	Rouvier, Le Lait, p. 209			..	Yes.	A farmer nursed his son sick with typhoid; twenty-one days later typhoid became epidemic in two institutions supplied by him with milk, as well as in most of the families he supplied.
Jan., 1895	Great Harwood.....	Sargeant.....	Br. Md. Jr., '95, i., 1,110	80	80	5	Yes.	Forty-nine families involved, being one-third of all supplied by this milkman. A man suffering from typhoid fever had been working in the dairy during all of January.
April to May, 1895	Stamford.....	Smith.....	Rep. on the Stamford Typhoid-Fever Epidemic.	386	376	22	No.	Evidently due to washing milk cans with contaminated water. Origin of typhoid contamination not discovered.
May to June, 1895	Plumstead.....	Davies.....	Br. Md. Jr., '95, ii., 1,561	177	159	23	No.	
Nov., 1895	Providence.....	Swarts.....	Monthly Bul. R. I. Bd. of Health, Dec., 1895.	30	30	3	Yes.	A boy working at dairy, who had recently driven a night-soil wagon, became sick with typhoid fever in the middle of October. A sister of the boy was taken sick ten days later. Their mother nursed them and washed the dairy utensils, including a cloth strainer.

TABLE SHOWING SCARLET-FEVER EPIDEMICS DUE TO MILK CONTAMINATION.

Date.	Town.	Reported by	Reference.	Total Number of Cases.	Cases among Drinkers of the Infected Milk.	Deaths.	Was Scarletina Found among the Milk Handlers?	Remarks.
1882	Greenock.....	Wallace.....	Br. Md. Jr., '82, i., 437; '82, ii., 1,323	47	12	..	Yes.	Cases traced to one milk supply and four cases found in milkman's children.
1883	Dundee.....		Br. Md. Jr., '83, ii., 839	17	17	4	Yes.	Milk sold in kitchen where boy was lying sick with scarlet fever. Seventeen cases occurred among drinkers of milk in four days. Milkman fined £5 and twenty days' imprisonment.
1883	Walborough.....	Health Officer..	Br. Md. Jr., '83, i., 78.			..	Yes.	Of sixteen families attacked nine were supplied by a milkman in whose family there was good reason to believe that scarlatina had existed.
1883	Kingston-upon-Hull...	Mason.....	Br. Md. Jr., '83, i., 334			..	Yes.	Child of milkman sick with scarlet fever. Five cases of scarlet fever found to have originated among consumers of this milk.
1882	Sunderland		Br. Md. Jr., '82, ii., 100			4	Yes.	Case of scarlet fever at dairy; four deaths among drinkers of the milk.
1882	St. Giles and St. Pancras	Power.....	Blyth, Public Health, p. 391			..	No.	Thought by Klein to be due to disease of the cow. The cases were traced to one milk supply.
1885	Marylebone	Blyth.....	Blyth, Public Health, 391			..	No.	Cases traced to one milk supply at Hendon.
1886 and 1887	Wimbledon and Meriton	Cooper.....	Br. Md. Jr., '89, 585. San. Record, '88-89, 422.	502		..	No.	Cases had a common milk supply. Seventy-four per cent. of all cases occurred within two days of stoppage of milk supply.
Jan. and Feb., 1888	Newcastle-upon-Tyne.	Armstrong..	Lancet, '88, i., 640	19	17	..	Yes.	Five and one-half per cent. of consumers on one milk route and nine per cent. on another attacked. Sudden outbreak and limited duration. Scarletina in one dairy worker some months before.
1888	Newcastle-upon-Tyne.	Armstrong.....	Lancet, '88, i., 640	116		..	Yes.	All in six days, involving sixty-three households.
1888	Garnet Hill.....		Br. Md. Jr., '88, i., 868			..	Yes.	Appeared first in dairy.
1889	Macclesfield.....		Br. Md. Jr., '89, i., 337	upward of 100		..	No.	Traced to one milk supply. In uptown district fifteen of twenty houses involved received contaminated milk.
Jan. 18, 1891	Bristol.....	Davies.....	Public Health, iv., 362	250		..	No.	Of 205 households 75 had common milk supply. In three districts one-fortieth of houses and one-seventh of those supplied by infected milk were attacked. Well-to-do people chiefly attacked; no cause found.
Feb., 1891	Cordworth.....	Hill.....	Public Health, iii., '91, 487	4	4	..	Yes.	Followed suspicious case at dairy. No new cases after stopping milk supply.
1891	Cordworth.....	Hill.....	Public Health, iii., '91, 487	17 houses	14 houses	..	No.	No cases at dairy.
1892	Leyton, Essex.....		Lancet, '92, ii., 733			..	Yes.	Sharp outbreak. Most of those affected supplied by a single milk dealer, in whose family was a case of scarlatina.
Mar. and April, 1892	London	Hammer.....	Lancet, '92, ii., 370			..	No.	Thought to be due to disease of cows. After milk was scalded no new cases occurred.
1892	Clapton	Warry.....	Lancet, '92, ii., 370			..	No.	Associated with a certain milk supply. Cows had high temperature and abrasions and cracks on teats.
Oct., 1892	Glasgow.....	Carpenter.....	Arch. Pediatrics, '94, 291	12	12	..	Yes.	
Dec., 1892	Glasgow.....	Chalmers.....	Br. Md. Jr., '94, i., 426	30	28	..	Yes.	These cases referred to two sources of milk supply. On farms from which milk came scarlet fever existed.

TABLE SHOWING SCARLET-FEVER EPIDEMICS DUE TO MILK CONTAMINATION—Continued.

Date.	Town.	Reported by	Reference.	Total Number of Cases.	Cases among Drinkers of Infected Milk.	Deaths.	Was Nariatina Found among the Milk Handlers?	Remarks.
Nov., 1893	Hastings.....	Wilson.....	Br. Md. Jr., '94, i., 815.....	26 houses	18 houses	..	No.	Seventy per cent. of houses invaded had one milk supply. Thirty per cent. of houses supplied by contaminated milk attacked. Cattle had febrile disturbance.
Oct., 1894	Sherley Warren.....	Health Office...	Br. Md. Jr., '94, ii., 956; Br. Med Jr., '94, ii., 1,458.	9	9	..	Yes.	A recovering case of scarlet fever under same roof as dairy, having access to dairy.
March, 1894	Blackheath.....	Murphy.....	Br. Md. Jr., '94, ii., 844.....	89	79	..	No.	March 14th, 3 new cases; 20th, 4; 21st, 17; 22d, 13; 23d, 19; milk supply stopped March 22d; no new cases after March 24th.
1894	Lewisbam.....		Diet. and Hyg. Gaz., '94, 246...			..	Yes.	Very extensive, sudden, and threatening. Traced to one dairy farm, on which several cases of scarlet fever existed.
Jan. and Feb., 1894	Richmond.....	Rowland.....	Br. Md. Jr., '94, i., 1,325.....	55	52	..	No.	Epidemic lasted ten days. Milk supplied from a filthy farm. Cows had to wade through liquid filth knee deep.
Feb., 1895	Stroud Green.....	Clothier.....	Br. Md. Jr., '95, i., 543.....	200	187	0	Yes.	Of sixty cases in hospital fifty-eight had had suspected milk. On January 8th, case of scarlet fever on a supplying farm followed by a bad sore throat in the nurse.

TABLE SHOWING DIPHTHERIA EPIDEMICS DUE TO MILK CONTAMINATION.

Date.	Town.	Reported by	Reference.	Total Number of Cases.	Cases among Drinkers of Infected Milk.	Deaths.	Was the Disease Present among the Milk Handlers?	Remarks.
Nov., Dec., '82-Jan., '83	Hendon.....	Power.....	Lancet, '83, ii., i., 145.....	79	55 (?)	..	No.	Seven-tenths of houses attacked had suspected milk supply. Cans were washed in sewage-polluted water.
April, 1893	London (suburb).....	Mackenzie.....	Br. Md. Jr., '84, i., 874.....	9 houses	9 houses	..	No.	Occurred in scattered houses.
1893	Cardiff.....	Paine.....	Br. Md. Jr., '83, i., 873.....			..	No.	Diphtheria among consumers of a certain milk. The well at the dairy contained an excessive amount of sewage. After closing the well there was no more diphtheria.
Dec., 1883	Davenport.....	Parsons.....	Br. Md. Jr., '83, i., 876.....	31	31	5	Yes.	Early in December diphtheria occurred in house next to the dairy, the privy of which was separated only by a partition from the room where the milk cans were washed.
Oct., 1886	Yorktown and Cambridge.....	Power.....	Practitioner, xxxix., 65.....	140	124	16	No.	Ninety-three per cent. attacked between October 8th and 18th.
June and Aug., 1886	Melrose.....	Clark.....	Br. Md. Jr., '87, cxvii., 100.....	23	23	..	Yes.	Milk obtained from family in which diphtheria existed.
June and Aug., 1886	Malden.....	Clark.....	Br. Md. Jr., '87, cxvii., 100.....	27	13	..	Yes.	Source of milk same as in Melrose epidemic.
Oct. 10 to 14, 1886	Frimley.....		Milch Zeitung, '86, 835.....		70	15		Thirty families involved. Milk from a high-class dairy; no trouble found there.
May to Aug., 1890		Jonsberg.....	Jahrsb. d. Ges. Med., '94, ii., 208.	16	6	..	Yes.	Three cases probably arose from visiting a girl sick with diphtheria at milk store.
Dec., 1890	Surbeton.....	Coleman.....	Br. Md. Jr., '91, i., 44.....	27	27	3	No.	Twenty-two houses invaded.
Oct. to Dec., 1893	Croyden.....	Philpot.....	Br. Md. Jr., '94, i., 474.....	97 houses	65	..	No.	Two-tenths per cent. of houses invaded and twelve per cent. of houses supplied by contaminated milk invaded. Three cows with eruption on teats found at farm.
June to July, 1893	Highstown.....	Hunt.....	N. J. R. of H. Rep., '93, 481.....	51	43	12	Yes.	Boy employed at dairy had diphtheria.

TABLE SHOWING OTHER EPIDEMICS DUE TO MILK CONTAMINATION.

Disease.	Date.	Place.	Reported by	Reference.	Total Number of Cases.	Cases among Drinkers of Certain Milk.	Deaths.	Did Disease Exist among the Milk Handlers?	Remarks.
Foot-and-Mouth.	1884	Dover.....	Robinson ..	Br. Md. Jr., '84, i., 570..		130		..	Foot-and-mouth disease existed among the cows at one of the dairies supplying the milkman.
Foot-and-Mouth.	1884		Vincent ..	Br. Md. Jr., '84, i., 575..	Consid. number		2		Diagnosis somewhat indefinite. Foot-and-mouth disease prevalent among cattle in neighborhood.
Throat Affection.	1881	Aberdeen.....		Br. Md. Jr., '81, i., 657..	300		3	No.	Of one hundred and ten families supplied by one dairy at least ninety were affected.
Throat Affection.	March, 1880	Rugby.....		Br. Md. Jr., '81, ii., 415..	100			No.	Involved three of the eight boarding-houses of the school; thirty boys in each were affected, all supplied by the same milkman. Fifteen out of thirty-seven families supplied by the same milkman had one or more cases. All cases occurred between March 16th and 18th.
Sore Throat and Erysipelas.	March and April, 1890	and Craigmores.....		Glasgow Med. Jr., '90, xxxiv., 241.	80		4	Yes.	Traced to a milk supply which was stopped April 2d, cases ceasing almost immediately. May 6th the supply was resumed, but fresh cases occurred, so the supply was again stopped. Farmer had erysipelas at this time, and a dairy-maid had sore throat from March 10th to 17th.
Gastro-enteritis	Nov., 1894	Manchester.....	Niven.....	Br. Md. Jr., '95, ii., 1,073.	160	160	0		Involved fifty per cent. of houses served by the milkman. Lasted only a few days. Filthy condition of dairy. A cow at the dairy had garget.

TABLE SHOWING OTHER EPIDEMICS DUE TO MILK CONTAMINATION—Continued.

Disease.	Date.	Place.	Reported by	Reference.	Total Number of Cases.	Cases among Drinkers of Certain Milk.	Deaths.	Did Disease Exist among the Milk Handlers?	Remarks.
Gastro-enteritis.	1892	Giesseu	Gafky.....	Deut. med. Woch., '92, xviii., 14.	3	3	0		Traced to a cow suffering from hemorrhagic enteritis. The same bacillus was isolated and cultivated from the cases and the cows. This bacillus was found to be pathogenic for mice and guinea-pigs.
Poisoning by Milk.	1887		Firth	Practitioner, '87, xxxix., 75.	9	9	0		Occurred in a hospital. Nine out of ten men were affected with nausea, vomiting, dryness and intense constriction of fauces, vertigo, colic, and purging. A residue extracted from the milk produced similar symptoms.
Poisoning by Milk.	Aug., 1886	Long Branch.....	Newton and Wallace	Rep. B. of H., N. J., 1885-86.	73	73	0		Nausea, vomiting, cramps, and collapse. Recovery in a few hours.
Poisoning by Milk.			Madson.....	Schmidt's Jahrb., vol. ccv., p. 131.					A whole family was attacked with diarrhoea and bloody stools after drinking milk from a cow similarly affected and with hæmaturia. The cow was supposed to have eaten a poisonous plant.
Cholera asiatica.	1887	India	Simpson	Practitioner, xxxix., p. 144.	11	10	4		Milk adulterated with water from a tank which had been the source of a cholera epidemic in the neighborhood.

Long Branch in 1885.³⁹ On the 7th of August forty-three persons at two different hotels were attacked with nausea, vomiting, cramps, and collapse from one to four hours after taking the milk. They recovered in a few hours. A week later thirty people at another hotel had the same experience. All these people had milk from the same source and only milk drinkers were attacked. The dairy and cattle showed no cause for criticism except that the milking took place at midnight and noon, and the milk was not cooled but was carted immediately to Long Branch, eight miles distant. In this case the test for the so-called tyrotoxicon of Dr. Vaughn was applied with a positive result. Another case of so-called ptomaine poisoning is reported by Firth.⁴⁰

In summing up we may conclude that infection by milk is well established in typhoid fever, scarlatina, diphtheria, tuberculosis, cholera, foot-and-mouth disease and acute enteritis, and that it may exist in anthrax. Cases of acute poisoning from milk by some undetermined agent also occur. Medical literature furnishes us with reliable evidence of an immense amount of sickness and a considerable death rate caused by milk. The recorded epidemics are but a part of those which occur. Many epidemics are never traced to their source and some which are so traced are not reported. This sickness and death directly due to contaminated milk is to a great extent preventable by proper legislation concerning the inspection of dairies and the handling of milk.

A Study of these Epidemics Teaches Us—1. Whenever a case of communicable infectious disease is reported inquiry into the source of the milk supply should be made.

2. Milk traffic should be separated from houses where people live. The dairy building should be at least one hundred feet from either the house, barn, or privy, and should be on a higher level than any of these, and should have a pure water supply of its own. At this dairy building all the dairy work should be done, including the cleansing of pails and cans.

3. It should be unlawful for any one who has come in contact with a sick person (when this sickness is not positively known to be non-contagious) to enter the dairy building or barn or to handle the milk.

4. All men connected with the milk traffic should be compelled to notify the authorities on the outbreak of any disease in their respective abodes and to abstain from their work until permission to resume is given them by the authorities notified.

5. Cities should accept milk only from dairies which are regularly inspected and where all the cows have been tested with tuberculin and those giving the

characteristic reaction have been killed and the premises disinfected.

6. The tuberculin test should be applied to all cattle and those which react should be killed, the owner being reimbursed from State funds. The premises on which such tuberculous cattle have been kept should be thoroughly disinfected. All cattle which are brought into the State should be quarantined until the tuberculin test has been applied.

7. The use of one long trough for the purpose of feeding many cattle should be avoided, since it is a ready means for the conveyance of pathogenic germs from one animal to another.

From the excellent regulations of the New York City Board of Health for the sale and care of milk I take the following important rule: "Milk shall not be kept for sale or stored in any room used for sleeping or domestic purposes or opening into the same."

Undoubtedly the adoption of the above regulations would do much in reducing the amount of sickness due to the conveyance of pathogenic organisms by milk. It does not seem probable, however, that any regulations can entirely eliminate this danger.

I would, therefore, add one word of caution for physicians who order milk diet. Use some sufficient sterilizing process, so that in case the milk supplied contains pathogenic organisms, they may be destroyed before the milk is used by the patient.

A CASE OF EXCISION OF BOTH UPPER JAWS, OF BOTH MALARS, OF BOTH PALATINES, OF BOTH NASALS, OF BOTH INFERIOR TURBINATED, OF THE ETHMOID, OF THE VOMER, OF THE LEFT LACHRYMAL, AND OF A PORTION OF THE PTERYGOID PROCESS OF THE SPHENOID FOR THE REMOVAL OF A RECURRENT OSTEOCHONDROMA.

By A. C. BERNAVS, A.M., M.D., M.R.C.S. ENG.,

PROFESSOR OF ANATOMY AND CLINICAL SURGERY AT THE MARION-SIMS COLLEGE OF MEDICINE IN ST. LOUIS, MO.

I AM about to record the most extensive surgical operation on the face that I have ever performed. The literature of surgery does not show a similar one, and I report it because it is of great interest in demonstrating the wonderful tolerance which is shown by the organism against the most severe and mutilating operations performed on the bones and tissues of the face, and also to encourage surgical interference in malignant disease in this region by this example of great relief given in a most aggravated instance.

In nearly twenty years of surgical practice I have operated on forty-one cases of tumors of the superior maxillary bones requiring total excision of this bone. In a few cases, the orbital plate was left and in some others more than the superior maxilla was removed. In three cases, including the one I am about to describe, both superior maxillaries were removed. Cases of epulis and small tumors of the alveolar process are not considered in this report. I have known some very small ones involving nothing but the gums and the alveolar process to give rise to enormous growths, if the primary operation was followed by a return. I desire to consider in this report the surgery of those only which necessitate extensive excisions and resections. Of the forty-one cases thirty-six were of malignant tumors, twenty were certainly carcinomata, twelve were sarcomata, and four were of such a structure that I was left in doubt after examining the sections. This was particularly the case with one tumor, a melanoma, which was remarkable for being so thoroughly infiltrated with pigment that a structure could not be made out at all in many places. Even the submaxillary glands in this case were so black and so friable when hardened that a structure could not be made out.

There were two deaths following operation, one a death upon the operating-table. In that case the tumor had pushed the eyeball entirely out of the orbit and the mass was found to extend into the cranial cavity, having grown through the horizontal plate

of the ethmoid. The other was death from shock about twenty-four hours after the operation.

In these malignant cases the final results were very different. In some few there was immediate recurrence; in others a long period of health was followed by recurrence or metastasis; in one-third, twelve cases, there was no recurrence for more than two years and these may be safely considered cured.

Of the five benign tumors two were large osteomata, one a fibroma, one a cystic odontoma, and one a hyaline enchondroma. All of these made permanent recoveries.

History of the Case.—M. S.—, thirty-two years of age, married, farmer, was sent to me from Oswego, Kan., by his physician, Dr. George S. Liggett, and arrived in St. Louis July 6, 1892. I sent him to the City Hospital and he was kept under observation there for eleven days before I performed the operation. Photographs were taken of him and two views are presented with this paper, Figs. 1 and 2, which were taken before the operation, and also a photograph, Fig. 3, taken after his recovery. Dr. H. H. Born and Dr. John Stack, the two senior assistants at the hospital, rendered most valuable services in this case. This history is from notes taken by Dr. Born.

There was no history in the family of any abnormal growth in any of its members. Patient had no ail-

FIG. 1.—Front View.

ment of any kind, had devoted himself to farming, had always been robust and healthy. His habits had been very good, his hygienic surroundings of the best; he drank and smoked but very little.

About April, 1891, the patient noticed an abnormal growth of the upper jaw, which growth gradually began to protrude from the mouth under the upper lip. When he first realized the seriousness of the affection the growth was about the size of a pigeon's egg. It was operated on in Kansas for the first time in June, 1891, and is said to have then been of the size of a small orange, diameter about two and a half inches. The operation had for its object simply the removal of the tumor by excision. By December, 1891, it had again reached its former size. It was removed a second time, the operation being similar to the first one. The growth began to return and in about four months had reached the size shown in Figs. 1 and 2, which are from photographs taken in the hospital in the month of July, 1892. The large tumor involved nearly the whole face, including the superior maxillaries, the palate, the

nose, the malars, and all the soft parts surrounding these bones. The growth was somewhat larger upon the left side than upon the right. Protruding and filling nearly the whole oral cavity was a large tumor, dense in structure, very slightly movable, and somewhat elastic, with a hard coating of dried purulent discharge.

The operation was performed, July 17, 1892, in the following manner:

Tracheotomy was performed below the isthmus of the thyroid gland; the patient was chloroformed there-

FIG. 2.—Side View.

after by means of the Trendelenburg apparatus. A large sponge with a ligature was then pushed back over the tongue and packed into the pharynx in order to prevent the entrance of blood into the larynx and œsophagus.

The first incision was made beginning at the right angle of the mouth and extending three inches outward and upward in the direction of the zygomaticus major muscle to the malar bone. All the tissues were then dissected away from the bones and from the tumor on the right side of the face as high as the external angle of the eyelids. The tissues in the orbit were then separated by means of a Langenbeck periosteal elevator from their attachment to the floor of the orbit.

Next the diseased skin of an area of more than two square inches was removed from over the left superior maxillary bone. An incision near the left angle of the mouth, beginning in the wound of the cheek, was then made through the upper lip. The nose and the remaining skin on the right side were then separated from their attachments to the bone and the tumor. The contents of the orbit on the left side were freed from the floor of the cavity just as they had been on the right side, care being taken not to injure the eyeball.

Both malars were separated from the frontal with the strongest bone forceps, the two nasals from the frontal, and with the chisel the pterygoid process of the sphenoid was broken off. The whole mass was then rolled out over the frontal region and this extirpation or evulsion of the whole mass did not give rise to any serious hemorrhage. The perpendicular laminae of the ethmoid and of the vomer, parts of the lateral masses of the ethmoid, and the lachrymal bone of the left side, were included in the mass, which was now removed by snipping off resisting spiculae of bone and mucous membrane of the naso-pharynx. On the right side a

portion of the malar and external wall of the antrum were left, because they were clearly free from the growth. All irregularities of tissue and all suspicious shreds were now trimmed off with scissors, leaving in the end a clean, enormous cavity, which was dusted with iodoform powder and temporarily packed with gauze.

The flaps of Schneiderian membrane hanging down from the horizontal plate of the ethmoid and the mucous membrane of the roof of the pharynx and nasopharynx were stitched together with fine silk sutures. The flaps of skin of the cheeks, nose, and upper lip were replaced and carefully stitched together with numerous sutures (see Fig. 3).

The whole upper face cavity was now filled with iodoform gauze, the ends of the strips being allowed to project through the nostrils, which formed good drain holes in the veil of skin which hung down like a mask from the forehead and orbits. The tumor which protruded from the mouth appeared to be cartilaginous. The left antrum was one solid mass of bone which protruded into the nasal cavity and had caused displacement and erosion of the vomer and septum of the nose. The teeth were loose in their sockets and their roots were surrounded by a pulpy cartilaginous growth.

The after-treatment was very troublesome. Patient was fed through a stomach tube for forty-eight hours, and after that he was fed through a pharynx tube for a long time, until he learned to eat and drink after a fashion peculiar to himself.

The patient gained rapidly in health and strength. He expressed himself as exceedingly thankful and was no doubt much pleased at the result. I think that his improvement and satisfaction were largely due to the removal of the offensive and disfiguring mass. Fig. 3 shows him to be anything but a thing of beauty and it is by far the best view that could be given of him. A profile would show a deep and "aching void" where the projection of the face ought to be.

Patient had fully recovered and left the hospital August 22d. "The wound on left cheek is open and

FIG. 3.—After Operation.

will require a plastic operation" are the last words in the hospital record on the day of his dismissal. May 15, 1893, ten months after the operation, word was received at the hospital that the "cancer was returning."

I received several letters from the patient during the six months following his departure, in all of which

he maintained that he was well and refused on account of lack of funds to return for the plastic operation. Dr. Liggett wrote me about a year after his return home that there was a recurrence and has since told me that the patient died in 1894, but I could get no further details of the termination of the case.

That this operation, formidable and mutilating as it no doubt was, conferred great benefit upon the patient and prolonged his life, will be admitted by every surgeon. Furthermore, that no kind of "toxins" or "cancer serum" could cause the absorption of bone and cartilage will probably be admitted also by even the most sanguine and hopeful of the promoters of the serum therapy of malignant tumor.

ST. LOUIS, February 16, 1896.

THE SUCCESSFUL TREATMENT OF DIPHTHERIA WITHOUT ANTITOXIN.

By E. ALEXANDER, M.D.,

JUAREZ, PASO DEL NORTE, MEXICO.

It is with diffidence, indeed, that I write at this time and in this generation on the treatment of diphtheria with remedies from the *materia medica*.

I feel as if I were compelled to introduce this article with an apology. Mentally I see some metropolitan physicians smile about the "country doctor who takes it upon himself to defend the '*materia medica*' against the horse.

I am not prejudiced against the so-called antitoxin. Many very conservative, highly able, and successful practitioners in the whole civilized world speak in favor of the new treatment; however, there are here and there just as conservative, just as learned, and just as prominent practitioners who do not endorse the new remedy.

It will not be amiss to remark that only a few short years ago highly successful and learned practitioners sang the pæans of various remedies which came from the bacteriological laboratories of France and from the *farbenfabriken* of Germany, and which are now dead, buried, and forgotten. To tell the truth, the writer does not like the commercial aspect of the antitoxin business. Almost every mail carries wagon loads of circulars from the different manufacturers of the diphtheria specific to every physician in the remotest corners—every house claiming to have its own peculiar mode of preparing the stuff.

Many of the medical journals have prominent and flashing "ads" from practising physicians, probably from a graduate of a '94 or '95 class, none of whom treated less than from seventy-five to two hundred and fifty diphtheria cases during the past few months, with no deaths. Great care is taken to interlard the reports with information as to which manufacturer the antitoxin came from.

A physician in actual practice for twenty-five years or even less knows from experience that many classes of diseases appear sometimes for several consecutive years in a very mild form; at other epochs they act with violent malignancy.

Reading English, German, French, and Spanish medical literature, the writer has noticed that diphtheria in the majority of cases has appeared for some years past in a very mild form throughout Europe, in the United States, and in Mexico, which is probably the reason of the proclaimed success of the new treatment. The writer has been practising his profession at Paso del Norte, Mexico, since 1874. This place has a population of some eight or ten thousand inhabitants. Some of the time there was no other regular physician within hundreds of miles. He has seen

many cases of tonsillitis and chronic follicular pharyngitis and of other kindred diseases among the Mexican population; in fact, such diseases appeared among all classes at different times as regularly as the different seasons appear; but he never saw a genuine diphtheria case even of the most simple variety until 1883 or 1884, or about a year after the introduction of sewer works at El Paso, Tex.

Dr. Samanago, a Mexican, a graduate of the *École de Médecine*, Paris, France, a highly polished, refined, practical physician, who has been practising off and on in this locality since 1856, informs me he never saw a genuine case of diphtheria at Paso del Norte until the year 1883 or 1884.

Father Ortiz, about ninety years of age, the parish priest of Paso del Norte, who has been about here more than half a century, an intelligent gentleman who studied a regular course of medicine to enable him to treat the poor of his parish, informs me that he never saw a case of diphtheria here until El Paso, Tex., introduced the sewer works.

Incidentally I make these remarks because only a short time ago I saw that a writer in one of the medical journals claimed that sewer works has absolutely nothing to do with the causation of diphtheria.

I am not going to argue this question here at length, but will remark that the results of the lack of proper attention to the excretions of humankind are exactly like those brought about by the presence of sewer works.

During the seasons the people here suffered from the various non-malignant diseases of the mouth and throat I employed the usual remedies applied in such cases—chlorate of potassium, tincture of chloride of iron, etc. Later on I adopted fluid extract of *phytolacca* with universal and quick success. When diphtheria made its appearance I stuck to *phytolacca* with the addition of aconite. I generally give from two to four drachms of fluid extract of *phytolacca*, according to circumstances, and one drop of tincture of aconite in a four-ounce mixture, of which the patient takes one teaspoonful every half-hour or hour. But the local treatment of diphtheria is all important, and I consider all internal medication of secondary importance. Generally I recommend gargles of a mixture of peroxide of hydrogen to those who can afford to buy the article; to the majority I give a solution of refined carbolic acid, eucalyptus oil, and tincture of iodine diluted with cinnamon water. Of this solution I order a tablespoonful in a wineglass of lukewarm water to be used as a gargle every five minutes. I instruct the mother, in the case of a child, to put a tablespoonful of this mixture in a small-mouthed earthen vessel containing about one pound. The vessel is filled with boiling water, the head of the patient covered with a towel, and the steam of the solution allowed to enter the mouth as long as it lasts. This is repeated three or four times a day, and sometimes at night.

I have treated hundreds of cases of malignant diphtheria during the past several years after the method here given, with prompt and complete recovery in all cases. Antitoxin can do no better.

Of course the bowels have to be attended to, and after the patient is convalescent a tonic treatment has to be continued for some time.

Tracheotomy is almost useless in diphtheria, because of the systemic poisoning which saps the strength. It is not the want of oxygen which kills the patient here, but the absolute debility from systemic poisoning.

In treating diphtheria we have two objective points—to destroy the bacillus creating the diphtheritic membrane and to combat its effect.

There is more joy over one patient that payeth than over ninety and nine dispensary cases that need not pay.

Progress of Medical Science.

Etiology of Idiopathic Hypertrophy of the Heart.

—After a brief history of the clinical recognition of hypertrophy of the heart, Dr. Whittaker proceeds to classify this condition according to its etiology, as follows (*International Medical Magazine*): (1) Hypertrophies due to obstacles in the heart itself, typically represented in valvular disease; (2) hypertrophies due to increased resistance in the vascular system; (3) hypertrophies due to disease of the heart muscle itself; (4) hypertrophies due to affections of the nervous system. The author passes over the hypertrophy due to valvular disease as not being idiopathic, and after a short allusion to a variety described by Germain Sée as the "hypertrophy of growth," in which there is a precocious development of the heart under tardy development of thorax, the hypertrophy of pregnancy is considered. During pregnancy the heart has been shown to increase in weight. The enlargement affects both ventricles and the walls as well as the cavities (Dreyse), and is most marked in young life and least in emaciated women. The cause of this hypertrophy is to be attributed to the increased work thrown on the heart in supplying the mammae, uterus, and placental circulation. Moreover, Spiegelberg, Gescheidler, and Heissler have shown in animals that there is an actual increase of blood during pregnancy. Hypertrophy of work is then dealt with, and Bolinger's investigations are quoted to show that animals with greatest muscular power are endowed with greater development of heart muscle. Hypertrophy due to resistance in the vascular system is introduced by a study of plethora, but it is probable that plethora alone is not sufficient to cause hypertrophy. Alcohol tends to produce the condition in several ways, such as by its action on the arterioles and nervous system and also by increasing the quantity of blood. Anything which favors the development of arteriosclerosis also precipitates the changes of age. These causes are chiefly alcoholism, syphilis, Bright's disease, diabetes, gout, saturnism, and psychical influences. Hypertrophy occurs in the various degenerations due to myocarditis, but is always preceded by dilatation. Hypertrophy due to nervous influences may be caused by mechanical irritation of the vagus and another common example is met with in Basedow's disease, though here dilatation is usually the more prominent symptom. Examples of chemical irritation of the vagus occur from excess of alcohol, coffee, tobacco, tea, etc. From whatever cause it may occur, hypertrophy of the heart is differently interpreted by pathologists. It is by the clinician spoken of as a compensatory process, and as such is looked upon with favor. Certain pathologists, however, of the modern school do not look upon it as ever physiological, but always as an indication of disease, and it is said that the great mass of men who have hypertrophy die from insufficiency. A more thorough appreciation of the causes which lead up to hypertrophy of the heart would enable us to recognize its insidious development more plainly and enable relief to be given.

Treatment of Perforating Ulcer by Nerve Stretching.—Dr. Chipault reports five cases of perforating ulcer successfully treated by stretching of the plantar nerves. After many unsatisfactory attempts to deal with this affection by amputation, excision of the ulcer, and scraping, the idea occurred to the author that stretching of the nerves distributed to the region occupied by the perforating ulcer might give some good results. Rejecting cases of non-trophic perforating ulcer which may be regarded as unamenable to

this plan of treatment, he tried nerve stretching with an unexpected degree of success in two cases in which the perforating ulcer was due to peripheral neuritis, and in three others of spinal origin. The five patients, all of whom had suffered for many years and undergone useless amputation, were in the course of a few days after stretching of the plantar nerves relieved of the ulceration and of the concomitant trophic disturbances. As four patients were kept in bed for only twenty-four hours after the operation and the fifth was thus confined for eight days, these good results could not be attributed to the rest which so often effects a transitory improvement in cases of perforating ulcer. These patients have remained quite free from their affection after intervals from the date of operation of eight, seven and a half, seven, six, and three months. The author has practised stretching twice of both the internal and external plantar nerves, once of the internal plantar alone, and twice of the internal collateral nerve of the great toe.—*La Presse Médicale*.

Intermittent Pneumonia.—In the *American Journal of the Medical Sciences* we are told that Dr. Mader has reported the case of a physician, forty-one years old, who was suddenly seized with a chill followed by fever, headache, and bilious vomiting. As influenza prevailed at the time, it was supposed at first that the patient had that disease, but on the second day Mader found physical signs of pneumonia in the left base. The disease lasted six days, with certain remarkable features. The temperature was intermittent, having five attacks lasting respectively forty-eight, twelve, fifteen, fifteen, and seven hours, rising almost to 104° F., alternating with intermissions of about twelve hours' duration each. The course was, therefore, somewhat like malarial quotidian, but not exactly like the latter, as the author says. There was neither chill nor sweating. Enlargement of the spleen in the attacks was doubtful. The infiltration seemed to recede in the first intermission, increase in the second attack, and then recede. After that the condition of the consolidation was masked by pleural exudate, but from the intermittence of the rusty sputum it seemed that the local process had an intermittent course. In addition there was periodic headache. Bacteriological examination of the sputum by Paltauf and Tannenheim showed diplococcus pneumoniae in almost pure culture. Streptococci and influenza bacilli were not present. Examination of the blood for malarial parasites was neglected. The author's explanation of this interesting case has at least the merit of boldness. The patient when a child had malarial fever for two years. After that he lived in Vienna, where malaria is rare, and never had malarial symptoms. Mader thinks that the parasites produce changes in the nerves or blood, which cause later disease to assume an intermittent character. As he says, "the belief that long-continued changes in the blood are produced by infection of various kinds is no longer strange," and it is also "well known that by frequent repetition the nervous system acquires automatic powers."

The Spontaneous Fracture of Uric-Acid Calculi.

—At a recent meeting of the Pathological Society of London, as reported in the *British Medical Journal*, Dr. Plowright read a communication on this subject. The patient was a man aged seventy-two, from whose bladder were removed two hundred and thirty-six fragments and six entire calculi in the process of spontaneous fracture. The base of the bladder was occupied by several sacculi or pockets about half an inch across, which contained the calculi, the fragments, and pus-laden urine.

The sacculi were formed by hernia-like protrusions of the mucous membrane between the reticulating

muscular fibres of the bladder, and were so placed as never to be emptied during life. The entire mass of calculi was mapped out into segments by elevated ridges and upon section each segment was seen to be lifted up, being separated from the nucleus below and from the other segments by cracks or fissures sufficiently wide to admit the point of a penknife. They were held together only by the ridges on the exterior of the calculus. These ridges consist of uric acid with a trace of ammonia, as pointed out to the author by Dr. Ord. The same substance in the form of a grayish-white deposit covers not only the exterior of all the calculi and fragments but extends into the interior of the fissures, covering their sides with a granular or nodular layer. Toward the outer extremities of the fissures, opposite the one or two outer concentric laminae of the calculus, it is deposited much more abundantly, so as to constitute an obtuse wedge when seen in section, by the increase of which the fissure is opened. The fragments are, as a rule, more or less wedge-shaped, but convex externally where they corresponded to the exterior of the calculus and concave internally when they have been lifted away from the nucleus. In some cases only one or two segments had been lifted out from a calculus. On the surface of the calculi the deposit often forms blister-like elevations which may be perforated in the centre and resemble volcanic craters. On section the upper wall of these blisters is seen to consist not only of the whitish-gray deposit, but fragments of the outer concentric laminae of the calculus have been upheaved by and remain embedded in it and are easily recognizable by their yellow color and striation. When pressure is applied to a calculus with sufficient force to crush it fracture takes place, not only by a separation between the concentric laminae, but also at right angles to them along what may be called the planes of radial cleavage. The tendency to radial fracture can often be observed in the sections of calculi in museums, but it is best shown in the structure of artificial calculi, as pointed out by Rainey in his book on "Molecular Coalescence." We may, therefore, regard a calculus as an assemblage of pyramids arranged with their bases externally. In the case under consideration the new deposit of uric acid on the exterior had taken place in such a manner as sometimes to lift up the outer laminae, sometimes to open the interpyramidal sutures. When once an opening has been made between two pyramids, the fissure spreads inward, the deposit acting as a wedge, so that the calculus becomes split in exactly the same way as a log of wood may be. The transverse section of an exogenous trunk presents many similarities to the section of a calculus. The pith answers to the nucleus, the annular rings to the concentric laminae, and the medullary rays to planes of radial cleavage. If a wedge be driven a short distance into such a log of wood parallel to its length and pressed forcibly sideways, it would lift a segment out of the trunk. The fissure between the wood fibres passes first inward toward the pith, but when the wedge is pressed sideways the fissure turns off at right angles, taking the direction of the annular rings for a certain distance, but if the sideways pressure of the wedge be continued the fissure will turn upward in the direction of the medullary rays and a piece of wood will be prised out. The process is identical in these calculi, the lateral pressure being caused by a wedge-like deposit. Rainey showed in the work above mentioned that when the artificial calculi formed by the action of potassium carbonate or solutions of gum arabic were placed in denser solutions of the colloid than that in which they were originally formed they tended to disintegrate. This is just what happened in the present case. The lower parts of the calculi

were continually immersed in the pus-laden urine of the pocket, while their upper portions were bathed in comparatively pure urine.

Carcinoma of the Displaced Cæcum.—Dr. Passler describes the following case observed in Curschmann's clinic. A man aged sixty was admitted with marked cachexia and symptoms of intestinal obstruction. As there was no evidence of the obstruction being due to syphilitic or tuberculous stenosis or adhesions producing kinking, or to a palpable tumor, a growth in the intestinal wall was diagnosed. It was localized by Curschmann in the right flexure of the colon, owing to the situation of the distended coils. No definite tumor could be felt, but a resistance was made out in the right loin. Operation was advised and the abdomen opened in the right hypochondriac region. The growth was found here apparently situated in the hepatic flexure. Resection was not attempted, owing to metastases, etc. An artificial anus was made, but the patient died. At the necropsy the growth was found in the cæcum, which was displaced upward. There was a total absence of the ascending colon, the cæcum passing directly into the transverse colon. There are, according to Curschmann's previous researches, two forms of displaced cæcum, namely: (1) that in which the colon is of normal length or even increased in length. Here the cæcum is so twisted that the fundus is directed toward the diaphragm and covers in a part of the ascending colon; or (2) the ascending colon is congenitally short or absent. The latter was the case here. The case shows that the clinical localization of the tumor may be influenced by the dislocation of the cæcum. Malignant growths in a dislocated cæcum have not in the author's knowledge been described. The possibility of a growth as well as of perityphlitic processes in a displaced cæcum should be borne in mind.—*Berliner klinische Wochenschrift*.

Cantharides in Albuminuria.—Dr. Lancereaux advises the use of cantharides in the anasarca following acute nephritis when the epithelial tissues are involved.

The Modern Aspect of Indicanuria, with Special Reference to the Relation between Indican and the Acidity of the Gastric Juice.—After a careful and exhaustive review of the literature, and after much original investigation on the indican reaction of the urine, Dr. Charles E. Simon, of Baltimore, summarizes his results as follows (*American Journal of the Medical Sciences*).

1. The gastric juice possesses antiseptic and germicidal properties.
2. These properties are referable to the presence of free hydrochloric acid.
3. A subnormal amount of free hydrochloric acid will call forth an increased degree of intestinal putrefaction.
4. The conjugate sulphates form an index of the degree of intestinal putrefaction.
5. The increased intestinal putrefaction in cases of subacidity and anacidity of the gastric juice is largely referable to an increased formation of indol.
6. The elimination of indican in the urine may be regarded as an index of the amount of free hydrochloric acid present.
7. A normal acidity of the gastric juice is never associated with increased indicanuria.
8. Cases of ulcer of the stomach apparently form an exception to this rule, an increased indicanuria being usually associated with hyperchlorhydria.
9. In other cases of hyperchlorhydria a subnormal or normal amount of indican is eliminated.

10. Simple constipation is rarely accompanied by an increased elimination of indican.

11. Diarrhœa referable to a catarrhal condition of the colon, often following a previously existing coprostasis, as well as diseases of the colon in general, is not associated with an increased indicanuria.

12. In the differential diagnosis between ileus and coprostasis, a small amount of indican excludes the former condition.

13. In cases of an achlorhydria with much lactic acid, the indican is not necessarily increased.

14. No indican, or but little indican, with delayed Gûnzburg potassium-iodide reaction, indicates the absence of free hydrochloric acid, with much lactic acid.

15. Much indican, with a normal or anticipating Gûnzburg reaction, is suggestive of ulcer.

16. In cases in which the use of the gastric tube is impracticable or contraindicated, or in cases of a mere superficial examination, the indican reaction will furnish a valuable index of the condition of the patient's digestive powers.

17. By means of the indican reaction we are enabled to follow very closely the results of treatment instituted in cases of gastro-intestinal disease.

Given as premises:

1. That a resorption of decomposing pus is not taking place anywhere in the body, as such a process itself is capable of producing an increased elimination of indican.

2. That there does not exist a stenosis of the small intestine.

3. A normal mixed diet containing no excessive amounts of red meats.

The author does not wish to convey the impression, however, that with the adoption of this method the use of the gastric tube for diagnostic purposes should be abandoned. From a careful analysis of the urine, it is true, many points of undoubted value can be obtained regarding the condition of the stomach, small intestine, etc., but nevertheless, the information thus obtained cannot as yet be so complete as that furnished by a direct examination of the stomach contents. As confirmatory evidence, however, and as a method to be employed when for any reason the use of the tube is either contraindicated or impracticable, the same will be found of decided value.

Metritis.—The *Jour. des Sc. Méd. de Lille* quotes from the new work of Dr. Douriez on this subject as follows: "In acute cases, absolute repose in bed, as for a fractured thigh, with vaginal irrigations; if blennorrhagic, dilatation of the uterus and iodoform pencil or swab; if puerperal, scraping or continued intra-uterine injections; if chronic, copious vaginal douches for three days, with mechanical dilatation of the uterus for five or six days, cleansing the uterine cavity and inserting a drainage tube the size of the thumb. This is removed every other day long enough to make an application of iodine inside the uterus. After three of these applications the drain is replaced by a vaginal tampon, which is left for four days. This treatment lasts for twenty days, when the patient may leave her bed. Any special treatment indicated by the neck of the uterus or by the pelvic basin must also be studied."

Syphilis in Infants.—Dr. Boulengier thinks syphilis cannot be transmitted by the spermatozoid. In cases of infants born with syphilis it has been acquired in utero. The disease may have been latent in the mother, but finding a good culture ground in the placenta it infects the offspring while sparing the mother. Though actual syphilis cannot be transmitted by the father, all the symptoms of degeneracy that it

entails may be inherited by the child. He supports his theory by a number of cases. One couple with no venereal antecedents of any kind had a child born with pronounced syphilis. The husband had contracted the disease when his wife was in the fourth month of pregnancy. A month after the birth of the child the mother was attacked with roseolar and papular eruption.—*Presse Médicale Belge*, November, 1895.

The Surgical Treatment of Dysentery.—Dr. E. L. Patterson, of Barnwell, S. C., in the Transactions of the South Carolina Medical Society (1894), calls attention to a mode of treatment for dysentery which in his experience has proven a specific and to which he applies the term "surgical." "I have observed," he says, "that there was a spasmodic contraction of the anus and this condition, I thought, was due to the irritation in the rectum, which excites the sphincters into firm contraction. The contracted condition of the sphincters, I concluded, prevented a complete evacuation of the contents of the rectum and thereby produced the tormina and tenesmus so characteristic of this disease. Having reached these conclusions, I determined to try dilatation of the sphincters and operated as for fissure in ano. The result was so gratifying that I have continued this mode of treatment and now immediately upon seeing a case, I dilate both the internal and external sphincters, but not quite to the extent as for fissure in ano. It is my custom to give a little chloroform, though I have operated on quite a number without doing so. The fever which accompanies dysentery is not the result of any inflammatory condition which exists in the rectum, for in the puerperal state we have a more inflamed condition and yet no fever, unless from sepsis, and we do not anticipate fever in our surgical operations unless from lack of antiseptics; therefore we must conclude that the source of fever in dysentery is the result of septic absorption. The after-treatment consists in irrigating the rectum with antiseptics and astringent solutions, although boiled warm water, one quart, with the addition of two drachms of powdered borax has given me as good results as anything else. After the dilatation of the anus the dysenteric evacuations cease. The internal treatment consists of the usual remedies, calomel, salol, and ipecac, in small doses repeated hourly until the physiological action of the calomel and ipecac is obtained, followed by a saline cathartic, being my preference, and if necessary, morphine, one-quarter grain, atropine, $\frac{1}{150}$ grain hypodermically, to relieve pain. The diet should consist of broth and raw eggs. As our water in the country is all surface water, I order boiled water for drinking purposes. The sanitary surroundings should be looked after and all of the evacuations should be disinfected. The room should be well ventilated and the bedding frequently changed."

Gonorrhœal Endocarditis.—The following conclusions are drawn from a study of the question by Finger, Ghon, and Schlagenhauser (*Arch. f. Derm. u. Syph.*, 1895, p. 323): 1. There exists a form of malignant endocarditis coming on as a complication of acute gonorrhœa and produced by the gonococcus. 2. The demonstration of the presence of the gonococcus in the vegetations of the endocardium by the process of culture fails, for the reason that the high fever which exists in these cases attacks the vitality of the specific micro-organisms. 3. The diagnosis can be made only by the microscopical examination of sections in which cocci present themselves in such a way as to remove all confusion. 4. The metastatic complications of gonorrhœa are produced through the vascular system

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, March 28, 1896.

THE VALUE OF MERCURIAL INJECTIONS IN THE TREATMENT OF SYPHILIS.

AMERICAN physicians—and by this of course we mean more especially those Americans who live in the United States and not in South America—have been reluctant to adopt as a general method of treatment that of hypodermic injections introduced by Lewin about thirty years ago.

In the discussions of the subject which have taken place in our important societies the consensus of opinion has usually been that hypodermic medication is not well adapted for office patients in this country and that we should reserve it for special cases, those apt to pass quickly from our control or to neglect all treatment at the earliest opportunity; and for certain hospital and dispensary patients. It is probable, however, that injections are coming more and more into favor here, as they are in France and Italy, while in Germany and Austria they would seem almost to have taken the place of older methods. Both soluble and insoluble preparations have their advocates, who claim superiority for their favorite preparation. The insoluble mercurials have lost many adherents in the past few years and in many quarters have been wholly given up. Dr. Renault, writing in the *Journal des Praticiens* of December 14, 1895, gives, as the chief arguments advanced in favor of the injection of soluble mercurials, that the dosage is mathematical and, being thus precise, we can obtain with small quantities curative effects superior to those resulting from larger doses introduced into the organism by other means; the therapeutic action is more rapid and more powerful; the injections are well borne by the organism and ameliorate the nutrition and general state of the patient; and, finally, they protect much more than other methods against recurrences.

The writer then proceeds to pick flaws in some of these claims and to point out a number of inconveniences and dangers which prevent the adoption of the method to the exclusion of others. The following indications for the employment of the injection treatment are formulated:

1. Soluble injections are applicable to cases of syphilis which are refractory to the usual methods of treatment. They then constitute a valuable resource which one gladly profits by.

2. There are patients whose digestive tube shows

an invincible intolerance for internal medication or whose skin inflames upon the slightest friction. These are surely entitled to hypodermic medication.

3. This method should be again employed when the physician is obliged to administer other drugs than mercury, with a view of combating at the same time other morbid states which call for special treatment. We can appreciate the interest one has in such cases to save the stomach as much as possible.

4. Finally, some cases of syphilis require by reason of their gravity an intense mercurial effect. We must rapidly influence the organism so as to draw away the severe and threatening manifestations from the ocular apparatus, from the nerve centres, or from some important organ. Here again the insoluble injections find their usefulness, although it is by no means proven that frictions applied according to the strict rules in patients capable of supporting them are endowed with a lesser degree of efficacy.

It is thus seen that some observers in European countries hold much the same views as the majority of those American physicians who have paid special attention to the subject.

OYSTER SHUCKERS' KERATITIS.

IN the *Johns Hopkins Hospital Bulletin* for November, 1895, Dr. R. L. Randolph described a disease which he called "oyster shuckers' keratitis," which occurs wherever the oyster industry exists, but which is particularly prevalent in Baltimore. That city, we are told, is the greatest oyster market in the country and there are at least six thousand shuckers in Maryland, oysters being prepared in that State for shipment elsewhere. The keratitis from which these men suffer is distinctly of traumatic origin. A minute particle of the oyster shell is chipped off by the hammer used in the shucking process and it falls into the eye. The particle is generally too small and too light to penetrate far into the cornea, and, unlike other foreign bodies, it can seldom be detected. This is due, according to Dr. Randolph, to the fact that a rapid infiltration takes place and the foreign particle is soon thrown off. The symptoms produced by the trauma develop very quickly. Photophobia is very marked. The patient says that he has a definite sensation of having been struck in the eye. This sensation is followed by pain some hours later and this pain is usually very intense. The central part of the cornea is rather more frequently injured than the periphery. The ulcer which is formed is very white, whiter than ordinary corneal ulcers. It is sharply circumscribed at its borders. It does not show the same tendency to spread that other corneal ulcers do, unless an infection has occurred.

As to the pathology of the trouble, Dr. Randolph has gone over the problem with great care and with very satisfactory results. He first attempted to discover whether there was any bacterial infection. A careful study made by inoculating tubes from the surface of the ulcer in sixty-five cases gave practically negative results. He concludes that oyster shuckers'

keratitis is not a parasitic disease. His next inquiry was to determine whether it had a chemical origin. A study of the effects of the action of the juice of the oyster upon the eye showed that this had no particularly bad effect. The further investigation, however, of the action of the oyster shell itself upon the cornea showed that the irritating properties were evidently due to the chemical constituents of this shell. The shell of the oyster contains over ninety per cent. of carbonate of lime. There are also sulphates, phosphates, silicates, and other mineral substances; organic matter is present to the extent of one per cent. The carbonate of lime is the principal constituent, and Dr. Randolph found that by taking pure sterilized carbonate of lime and applying it to a sterilized wound of the cornea a keratitis would result. He concludes, therefore, that it is the lime which has the specially bad effect in the causation of this trouble. The specific conclusion reached is that bacteria always play a part in traumatic keratitis, but in the variety of traumatic keratitis which occurs in oyster shuckers the cornea is made especially susceptible to micro-organisms by the irritating chemical ingredients of the oyster shell, notably the carbonate of lime.

As regards treatment, Dr. Randolph finds that the yellow salve is useless and that the galvano-cautery has no very specific effect. A compress bandage and a mild sublimate solution, 1 to 4,000, used every four hours, together with an occasional drop of a solution of atropine, gave the best results.

THE NUDE IN ART AND THE DRAMA.

THE preacher has often inveighed against the nude in art and especially against the nude in the theatre; the moralist shakes his head with a resigned protest; the rest of the world goes its way, perhaps, or says, "It is Art," and therefore must be all right.

Dr. L. M. Phillips, a physician of Penn Yan, takes the matter up statistically and proceeds to make some very distressing statements. He says, in the *Cincinnati Medical Journal*, that he has been asked this question:

"What influence does the nude statuary exposed in our public museums, and the nude or almost nude living pictures exposed in the *fin-de-siècle* theatre, have upon such organisms as the hysterical or those presenting peculiar or abnormal sexual phenomena?"

In answer Dr. Phillips says that as the result of his investigations he is "unable to find more than one per cent. who do not present an increased sexual desire at the sights referred to above. In more than sixty per cent. of the remainder, there is presented the desire to obtain at almost any cost the fetich. This class is not satisfied except the whole is obtained and attained. Here there is nothing psycho-pathologically wrong in desiring and obtaining the fetich, except the sexual accentuation, which is more or less a mild nymphomania in the female, and in the male satyriasis, which surely ebbs and flows when the sexual centres are appealed to. This class, it may be

said, make up our healthy sexual population, for they present nothing abnormal sexually. The other thirty-nine per cent. some time or other during their active sexual life present evidences of abnormal sexuality."

Tabulating these interesting figures we find the following:

Uninfluenced by the living pictures, etc. . . .	1 per cent.
Influenced.	99 "
Influenced by a desire to obtain the fetich. . . .	60 "
More or less affected at same time.	30 "

In illustration of these observations, Dr. Phillips reports some cases in which anæsthesia or hyperæsthesia sexualis was produced by viewing the fetich in its various types.

The conclusion reached is that such exhibitions, while quite harmless to the trained artistic mind, produce injurious sexual disturbances in a large percentage of the immature, uneducated, and neuropathic people who frequent the modern show.

SPECIAL MEDICAL ADVERTISING IN THE DAILY PRESS.

IN paragraph three of Article I. of that portion of the Code of Medical Ethics which treats of the duties of physicians to each other and to the profession at large, it states among other things that "it is derogatory to the dignity of the profession to publish cases and operations in the daily prints." The framers of this rule of action, conscious of human weakness in general and perhaps of the physicians' temptations in particular, went a step farther and added: "Or suffer such publications to be made."

Whether always justly so or not, New York affords an example in matters medical as well as in many other things that interest the people of this great country. We should, therefore, make an effort to so direct our actions that, if they are to be imitated, good rather than harm may result; and for this reason we believe an apology is due the profession at large for the manner in which some medical men who claim to represent special lines of work are being advertised in the daily papers. We do not mean to claim that a physician can or always should prevent his name from appearing in a proper way. Many general questions arise pertaining to public health which demand discussion by physicians. The public is at times entitled to the views of medical men upon matters which thus affect the general welfare. It is, however, another matter when a physician conducts a private institution, and this particular institution is described, and the brilliant operations performed within the privacy of its walls are statistically announced for the public good week after week. We cannot believe that men with brilliant reputations already established are knowingly guilty, having so little to gain and so much to lose in the good will of their colleagues. Perhaps a kindly disposed assistant may furnish the details of an operation to some friend upon the press, or perhaps the patient himself, possessed of an unusual amount of kindness of heart and surprising knowledge of technical details, may write it up as an acknowledg-

ment of his gratitude. The surgeon, of course, being too busy to trouble himself with measures tending to check it, the free advertisement goes on until he finds himself overrun with applications beyond the capacity of his establishment. One result of this unseemly publicity is to lead lesser lights into a spirit of dissatisfaction, prompting them to boom themselves, and, in the absence of a private sanitarium or special hospital to describe for the benefit of a longing public, they must content themselves with a before-and-after photograph of the patient whose remarkable case is described, and the location of the office where the "skilful operator" can be found.

The technical nature of the details indulged in by these gentlemen leaves no doubt that they have been their own advertising agents, and destroys all possibility of a charitable construction being placed upon the venture.

From a business standpoint we believe the newspaper-advertised physician in both these classes described is making a mistake. The one should take time to find out who is injuring him in a possible attempt to benefit, and have it stopped. The other should take his chances in striving to keep the respect of his fellow practitioners.

If one must thus keep before the public, let him do it in an out-and-out manly quack fashion at regular rates.

News of the Week.

Opening of the Columbus Hospital, New York.

—The Columbus Hospital on East Twentieth Street was formally opened March 18th. A large number of visitors was present. The reception lasted from 3 P.M. to 5 P.M., and the guests were received by the Salesian Missionaries of the Sacred Heart. Preceding the inspecting of the institution by the visitors, the hospital was blessed by Archbishop Corrigan, who also made a short address. The medical staff consists of Drs. Stephen Smith, George F. Shrady, John Boucher, Charles Lewis, Bache Emmet, Peter Callan, Frank Ferguson, Cornelius Cokeley, Ramon Guit  ras, and Joseph Winters.

Encouraging Words.—"Your issue of March 14th contains more news and valuable reading than any journal I have seen for a long time."—*E. L. Patterson, M.D., Barnwell, S. C.*

The State Clothes Tax.—Since our last issue the courts have decided against the demands of the Lunacy Commission for new clothes for patients transferred to the City Asylum; but the commission, jealous of its autocratic rights, has made an appeal from this judgment, making a compromise with the Commissioners of Charity by which the transferred patients can be furnished with clothes and temporary lodging, ultimately perhaps at the city's expense.

Obituary Notes.—DR. WINTHROP SARGENT, formerly a resident of Philadelphia, died on March 16th at Roxbury, Boston, at the age of seventy-four years. He was born at Gloucester, Mass., and was educated

at Dartmouth College, subsequently studying medicine in the University of Pennsylvania, from which institution he was graduated in 1847. He was surgeon in charge of the government hospital at Kingsessing in 1862.—DR. JACOB P. SCHOLL died at his home at Bethlehem, Pa., on March 15th at the age of eighty-one years. He was prominently identified with the industrial and commercial interests of the neighborhood in which he lived.

Orphan Asylum of Hebrew Sheltering Guardian Society.—The consulting medical board of the Orphan Asylum of the Hebrew Sheltering Guardian Society was organized March 15th with Carl Beck, M.D., as president, and William S. Gottheil, M.D., as secretary. The other members of the board are: Henry S. Oppenheimer, M.D., George H. Fox, M.D., Welcome T. Alexander, M.D., Joseph G. Wallach, M.D., H. T. Brooks, M.D., and Albert T. Swan, M.D.

Vital Statistics of the City.—There were 850 deaths during the past week apportioned as follows: Measles, 28; scarlet fever, 5; diphtheria, 28; whooping cough, 8; typhoid fever, 2; malarial fever, 2; meningitis, 4; diarrhoea, 17; heart disease, 60; croup, 9; bronchitis, 35; pneumonia, 165; phthisis, 104; Bright's disease, 48; violence, 31; other causes not given.

The Eastern Medical Society of New York.—At the March meeting of this society Dr. F. C. Valentine read a paper on "Posterior Urethritis," which was discussed by Drs. Louis Fischer and S. Brothers. Dr. Zanoni also made a psychological demonstration of much interest.

The Western Society of Eye, Ear, Nose, and Throat Surgeons will be organized at a meeting to be held at the Midland Hotel, Kansas City, on April 9 and 10, 1896. The programme of the meeting contains a long list of interesting titles. The acting secretary is Dr. Hal Foster, of Kansas City, Mo.

American Students in Paris will in the near future be received at the Medical School to compete on an equal footing with French students. The following resolutions will shortly become law, according to a statement just given out by Dean of the Faculty Brouardel:

"Every French or foreign student who wishes to be inscribed at the Facult   de M  decine will present the same diplomas, and will, in consequence, be on an absolute footing of equality.

"At the conclusion of his studies he will obtain the diploma allowing him to practise medicine in France.

"Those among foreign students who wish to obtain a diploma testifying only to the assiduity with which they have followed the usual course for medical students in France may receive a diploma *pro honores*, which will not allow them to practise medicine in France."

Dr. Guiseppe Cipolla, sanitary inspector in chief of the Italian army, died in Rome on February 14th. He was born in Montemaggiore, Palermo, on July 28, 1833. The cause of his death was nephritis.

Food Values.—Experiments to determine relative food values are being conducted by Professor Atwater and others under the direction of the United States government at Middletown, Conn. Dr. Tower, who has just completed a week's confinement in an air-tight room into which a measured quantity of air was pumped daily, has studied the effects of various articles of diet during his confinement, and his conclusions it is thought will prove of value.

Successful Candidates for the degree at Bellevue made the neighborhood of East Twenty-Sixth Street very lively for a few hours the day the results of their examinations were announced. This is as it should be. Their time for merry-making is fast drawing to a close. In a few years they will look back and wonder why they should have felt so good over it—and wish at the same time they had made things more lively while they were at it.

Cæsarean Sections are not of frequent occurrence in Tennessee, if the statement in the *Nashville American* of March 14th is to be trusted. An operation just performed near Huntingdon by a professor of gynecology in the Vanderbilt University is said to be the first one in that region and, so far as the writer was aware, in any part of the State. An interstitial fibroid in the lower segment of the uterus was the occasion for surgical intervention in a woman of thirty years who had already borne several children. The child died half an hour after delivery, but at the date of writing, three days after the operation, the patient herself, upon whom laparo-hysterectomy had also been performed, was doing well.

Deaths under Anæsthetics in England.—Five deaths under anæsthetics within the comparatively brief period of a week have been reported as occurring in various parts of England. In three cases chloroform was the anæsthetic employed, in one ether, and in one the anæsthetic is not mentioned by the *Medical Times and Hospital Gazette* which comments upon the cases. That such accidents are frequent is to be inferred from the opening sentence: "The list of deaths under anæsthetics continues to expand at an alarming rate." The jury in each instance appears well satisfied with the results. The verdict usually reads: "Death from failure of the heart's action, due to chloroform administered for the purpose of an operation, and that the chloroform was duly and properly administered," or, as in the inquest held upon the thirteen-year-old daughter of a clergyman who died while having a tooth extracted, a verdict is handed in "Death from misadventure." In this connection the following statement taken from the *Medical Press* is significant: "Sixty-one deaths have occurred during the administration of anæsthetics in the United Kingdom in the past year. Fifty-two of these have been due to chloroform."

The Health of the German Empress is reported to be in a very unsatisfactory state and her condition causes much anxiety. She is to go to Kreuznach as soon as the season opens and later to the island of Rügen in the Baltic.

Dr. P. Hedenius, professor of general pathology, pathological anatomy, and state hygiene at the University of Upsala, and president of the Upsala Medical Society, has recently died.

Yellow Fever prevails extensively in Rio Janeiro. A steamer recently arrived from there lost one of her crew from the disease shortly before reaching this port. For the two weeks prior to the steamer's departure from Rio Janeiro there were reported four hundred and fifty-one cases of yellow fever, with three hundred and ninety-five deaths.

Dr. S. Pozzi, the well-known gynecological surgeon of Paris, has recently been elected a member of the Académie de Médecine. It is said that the French government is about to establish a chair of gynecology at the Faculté de Médecine, and that Dr. Pozzi, who is already a *professeur agrégé*, will be its first incumbent.

Expulsion from the Medical Society of the County of New York.—At the last meeting of the society Dr. W. F. Grier was, on the recommendation of the committee on ethics, expelled for unprofessional conduct. Dr. Grier will, it is said, make an appeal to the courts for reinstatement.

The Cartwright Lectures of the College of Physicians and Surgeons for 1896 will be given by George S. Huntington, A.M., M.D., professor of anatomy in the medical department of Columbia University, New York. I. Lecture, Wednesday, April 8th.—"Morphology of the Ileo-Colic Junction and Large Intestine in Vertebrates." II. Lecture, Wednesday, April 15th.—"Evolution of Human Cæcum and Vermiform Appendix, and Probable Lines of Derivation of the Corresponding Structures in the Other Vertebrates." III. Lecture, Wednesday, April 22d.—"Morphology of the Bronchial System and its Relation to the Pulmonary Vascular Supply in Mammalia." The lectures will be given in the hall of the New York Academy of Medicine, 17 West Forty-Third Street, on the above dates at 8:15 P.M.

The California Northern District Medical Society held its semi-annual meeting at Red Bluff on March 10th. A number of interesting papers on hernia, chloroform anæsthesia, hygiene, mental therapeutics, and other subjects were read and discussed during the morning and afternoon sessions, while the evening was devoted to the discussion of a banquet at the Tremont Hotel.

X-Ray Spectacles.—It is reported that Mr. Thomas A. Edison has invented fluorescent spectacles which will enable the surgeon to see directly through any part of the body. The fluorescent medium is paper covered with the tungstate of calcium, and takes the place of ordinary lenses in the spectacles. By means of a portable machine containing an air-pump and Crookes' tube the rays are projected through a limb from its distal aspect and transfer the image directly to the eye of the observer. He calls his instrument the Fluoroscope, and claims that it can be adapted to hospital uses.

Health of London.—London now claims to be the healthiest of the large cities, the death rate being only 16.3 per 1,000 persons. The death rates in other large cities are: Berlin, 18.2; Paris, 20.5; Vienna, 22.5, and New York, 19.6.

Manslaughter and Typhoid Fever.—The Duluth Gas and Water Company has been indicted for manslaughter in having caused the death of Harry W. Smith by typhoid fever, alleged to have been contracted from water delivered through the mains. Their franchise specifies that they shall furnish pure water.

Seats for Employees.—The New Hampshire legislature has enacted a law compelling every person, firm, or corporation employing females in any manufacturing, mechanical, or mercantile establishment in the State to provide suitable seats for the use of females so employed.

Navy Department.—Bureau of Medicine and Surgery, Washington, D. C. Changes in the Medical Corps of the U. S. Navy for the week ending March 14, 1896. March 10th—Medical Inspector J. B. Parker to duty in charge of naval hospital, Widow's Island, Me., in addition to present duties. March 11th—Surgeon Thomas Owens placed on the retired list March 10th. March 13th—Surgeon W. R. Du Bose detached from the Naval Academy and ordered to the *Terror*.

Turbulent Students.—Whenever popular excitement runs high in any of the countries of Southern Europe the socialists and the students appear to vie with each other as to which can most effectually disturb the peace. At present the universities in both Italy and Spain are closed, those in the former country on account of the Italian defeat by the Abyssinians, those in the latter because of the popular rage against the United States.

Ether Narcosis and Danger from Fire.—At the Female Hospital in St. Louis recently, during the administration of ether, the latter took fire, causing some disagreeable burns. The accident followed as the result of forgetting that ether is very inflammable.

The St. Petersburg Medical Library.—The library of the Academy of Medicine in St. Petersburg takes in no less than one hundred and forty medical journals and reports in the Russian language and more than four hundred foreign periodicals.

Degeneration in Italy.—A Milanese writer says that "forty-five per cent. of Italian youths cannot complete their military service for physical decrepitude and the maladies it invites."

Oxford is Conservative.—The congregation of Oxford University has rejected by a vote of 215 to 140 a resolution to allow women to take the degree of bachelor of arts.

An Improved Antitoxin.—The Board of Health of this city announces that it is now manufacturing an antitoxin which is much stronger and consequently much more efficacious than any hitherto prepared. In a circular just issued it says that the

curative value is not due to the amount of serum but to the amount of antitoxin which the serum contains. The disagreeable symptoms are often produced by the serum itself. Consequently the more concentrated it is the smaller can be the dose and the less likelihood of eruptions, etc., following its use. To institutions the serum will be furnished free of cost and physicians can obtain it at cost of production.

Dr. W. M. L. Coplin has been elected professor of pathology and bacteriology in the Jefferson Medical College of Philadelphia. He is at present professor of pathology in Vanderbilt University.

Rice Cultivators in Italy.—In a recent medical report of Professor Celli it is stated that in the rice-fields around Ravenna, Italy, the workers, mostly females, are bowed nearly double, emaciated, with ashen-gray complexions, all to gain twelve cents a day, and their children are anæmic, tympanitic, and under-sized.

Menelek and the Red Cross.—King Menelek of Abyssinia has asked that his country be admitted to the Red Cross convention, and at his request the Russian Red Cross Society has sent to Abyssinia a number of surgeons and nurses with medical supplies.

A Trial of Cholera Inoculations.—During a recent cholera epidemic on the railway line from Assam to Burmah, one hundred and ninety-six workmen were inoculated after the method of Dr. Haffkine. Of these only four died, while of one hundred and fifty-nine who were not inoculated thirty died.

An Anti-Cigarette Law.—The Iowa legislature has passed a bill forbidding the sale or manufacture of cigarettes or cigarette material in Iowa. The penalty for the first offence is a fine of from \$25 to \$50, and for the second offence a fine of from \$100 to \$500 or imprisonment for six months.

Medical Journalism in Philadelphia seems to be very nearly of the past. The *Medical News* has left, the *Times and Register* is published there but edited in Boston, and the *Medical and Surgical Reporter*, which left there once and then returned, is administering weekly rebukes to its readers in that city for their lack of energy and their failure to keep abreast of the times. Surely, this cannot be so!

Accident to an Ambulance Surgeon.—While Dr. John H. Scholl, the ambulance surgeon of the Homœopathic Hospital, Brooklyn, was answering a call one night recently, the strap by which he was supporting himself broke, and he fell backward into the street. He was picked up unconscious by the driver and taken back to the hospital.

An Anti-Tobacco League is finding much favor among Philadelphia school boys. Of one thousand and thirteen boys in one school five hundred and fifty signed a pledge to abstain from the use of tobacco until they reach the age of twenty-one years.

Degrees Refused to Women.—The senate of Cambridge University, by a vote of 186 to 171, has rejected the proposition to appoint a committee to con-

sider the question of conferring degrees upon women. A similar decision had been reached by the authorities of Oxford University a few weeks before.

Against the Spitting Nuisance.—The health board of St. Louis has recommended to the city council the adoption of an ordinance making it a misdemeanor for any person to expectorate on the floors of street cars or other public conveyances, or in hotel corridors, theatres, public halls, and places of worship; also that the porters or persons in charge of the cars and public places be required to furnish cuspidors in sufficient number and that they be required to clean the vessels daily, using some disinfecting fluid to be approved by the Board of Health; also that suitable provisions be made for the inspection of the vessels and the public places where they are provided.

Accidental Poisoning.—Dr. M. C. White, New Haven's medical examiner, carried a bottle of aconite, which he had taken from a suicide's effects, in the same pocket with a bottle of cough syrup, and drank from the wrong bottle. Fortunately he received prompt assistance and his life was saved.

Bequests to Charitable Institutions.—The will of George Bliss, of the banking firm of Morton, Bliss & Co., of which Gov. Levi P. Morton is a member, has been admitted to probate. The following bequests are contained therein: Woman's Hospital in the State of New York, \$20,000; Hospital of the New York Society for the Relief of the Ruptured and Crippled, \$20,000; Manhattan Eye and Ear Hospital, \$10,000; and the Old Women's Home at Northampton, Mass., \$10,000.

New York Eye and Ear Infirmary.—Dr. James F. McKernon was appointed attending aural surgeon of the New York Eye and Ear Infirmary at the February meeting of the board of directors.

The Present Spring Weather.—The following is the *Sun's* racy tribute to our breezy spring, justly provoked by the allusion to "Sweet whispers in the air" made in a recent issue of the *Boston Transcript*: "Oh, you bards of Boston, with mufflers on your sensitive faces, tippets around your canorous necks, and a hundred thousand east winds whistling in your dazed and flaring ears! Spring whispers, does it? And of all springs, and vernal sons of bunco, spring in Boston. Spring doesn't whisper; it wheezes. It is full of rheumatism and ruin. Coroners march before it; even the reluctant poets of other climes than Boston hymn it with necks in noose of tonsillitis, and the music of the metre is palpably hampered by the coarse sobbing of goloshes. Be just and jeer not. Spring doesn't whisper; it roars and howls. It filches hats even from the stateliest elocutionary thoughttops. It fills the most reverent ears. It tips with crimson the most beautiful noses. It brings snow when it ought to bring baseball. It is full of snow that is too late, and of mud that is too thick."

Roentgen Pictures in Newspapers.—The powerful effect of imagination over that produced by actual fact is painfully illustrated in the efforts of the various

newspapers in their attempts to illustrate the anatomical details of the bony parts of the foot and hand as actually shown in the skiagraphs. With the exception of the copy of the hand made from the MEDICAL RECORD, the anatomical details are impossible and absurd. The Roentgen rays cannot lie, and it is very unsafe to make them do so. Any one who attempts false methods must always have a good understanding of his subject and have a good memory besides.

The "X" Rays and Bacilli.—The latest report is to the effect that bacilli enjoy the "X" rays and appear to thrive under their influence. Several bacteriologists are now very busy in reporting these results to the newspapers.

No Show for Brains by "X" Rays.—At the recent dinner of the Princeton Club, Professor Magie, in exhibiting skiagraphs of a goldfish, said: "These are the fish's swimming-bladders. That is about the way the interior of the skull would look if we should try to photograph it with the Roentgen rays."

The New Warden for Bellevue Hospital is a young plumber and friend of a prominent politician. There is a promise of his efficiency so soon as he makes a professional study of the capabilities of the institution.

Charge of Criminal Assault Dismissed.—The \$10,000 damage suit brought by Miss Cora B. Houseman, of the town of Stafford, against Dr. Ward B. Whitcomb, a physician of Batavia, N. Y., for alleged criminal assault, was dismissed on account of lack of evidence. We congratulate the defendant on his escape from a professional scandal.

Central Nervous Lesions in Diphtheria.—At the recent meeting of the Philadelphia Pathological Society Dr. J. Dutton Steele read a paper entitled "The Lesions of the Central Nervous System in Diphtheria," and presented illustrative sections and diagrams showing destructive changes in the dendrites and gemmulæ of the ganglion cells of the cortex cerebri of animals dead from inoculation with the toxin of diphtheria. The changes detailed corresponded closely with those previously described by Berkley as following poisoning with ricin and with alcohol. Dr. A. E. Taylor reported a case of pernicious anæmia, in which apparent recovery twice ensued after treatment with arsenic and bone-marrow, but which finally terminated fatally. Both hæmoglobin percentage and red-corpusele numbers fell at times to an extraordinarily low level, but the former never quite so low as the latter. The erythrocytes presented moderate poikilocytosis, slight microcytosis and macrocytosis, and distinct nucleation, and the viscera after death contained an excess of iron. There was a total absence of hemorrhages during life. The stomach was atrophic. Dr. Judson Daland presented an interesting specimen exhibiting a healed dissecting aneurism of the ascending arch of the aorta and at a short distance beyond a second formation of similar kind, which, however, had ruptured into the pericardium and induced the fatal result. Dr. Alfred Stengle exhibited kidneys of

which the suprarenal bodies seemed to form an integral part, and also a group of tuberculous and neoplastic adrenals unassociated during life with symptoms of Addison's disease.

Reception to Dr. A. Donaldson Smith.—Dr. A. Donaldson Smith, of Philadelphia, who has just returned from an African exploration, delivered an address before the Geographical Society detailing his travels and some of his experiences, after which a reception was tendered to him by the Penn Club.

Lunacy Commissions Not What They Should Be.—Dr. Henry P. Stearns, medical superintendent of the Hartford Retreat for the insane, in an able article on the supposed value of lunacy commissioners, says that in view of the present conditions, and until a brighter day dawns upon our system of civil service and a higher appreciation of the possibilities inherent in commissions is realized, we must look for advances in psychiatry mainly along other paths, some of which have already been outlined and entered upon by the physicians who have had large experience in the very limited conditions which have existed during the past half-century, rather than from any service likely to be rendered in the near future by boards of lunacy commissioners.

A Woman Physician in Colorado, who had bequeathed her body for dissection to a medical college, died recently, and her husband complied with her wishes in delivering the body to the college.

Measles in Connecticut.—The report of the Connecticut State Board of Health for February shows some striking variations of the epidemic of measles prevailing in many parts of the State. The town of Roxbury, with only 936 inhabitants, returns 84 cases; Ridgefield, with 2,235 inhabitants, 96 cases; Woodbury, with 1,815 inhabitants, 79 cases; and Darien, with 2,276 inhabitants, 74 cases. On the other hand, except Norwalk, the urban towns return almost no cases at all, and as showing further the localization of the epidemic, 59 out of the 168 towns in the State return not a single case of any contagious disease.—*Evening Post*.

Small-Pox in Cuba.—A despatch from Santiago de Cuba says that the people of that city are alarmed by the reports of ravages of small-pox in Manzanillo. The alarm is due to the ease and frequency of communication between the two cities. The bulk of the population is blacks and most of them are unvaccinated. With the rapid spread of the disease in Manzanillo and the absolute lack of precaution, the disease will continue to reach out and add to the general demoralization of the island.

An Income Tax on Lawyers.—The Louisville city council has before it a bill which provides for an income license tax on lawyers. The ordinance places a tax of \$100 on those lawyers who have an annual income of \$10,000 or over from their practice; from this sum the scale slides downward, \$10 being the amount of the lowest license, a sum which every lawyer, no matter how humble, must pay.

Philadelphia County Medical Society.—At the last meeting of the Philadelphia County Medical Society, Dr. C. A. Veasey reported the case of a young woman in whom violent toxic symptoms with delirium and paraplegia developed after the instillation into each conjunctival sac for cycloplegic purposes of one drop of a solution of duboisine, two grains to the ounce of distilled water. Dr. G. E. de Schweinitz read a paper dealing with the subject of the repair of lesions and wounds at the corneo-scleral junction. He reported a number of cases in which sutures had been employed under these conditions with entire success. In a second paper Dr. de Schweinitz discussed the question of the extraction of unripe cataracts, and reported twelve cases in persons from twenty-five to seventy-five years of age, in which he had successfully performed this operation.

No Professional Secrets in Michigan.—A judge has decided at Battle Creek, Michigan, that a physician must testify in regard to the ailments of his patients.

The Prevailing Disease among British Soldiers in India at the present day is typhoid fever. The mortality among them from this disease is said to be greater than the combined mortality from cholera and dysentery in former times.

Abdominal Section in an Infant.—Dr. Charles B. Kelsey (*New York Medical Journal*) reports a successful laparotomy for intussusception in a child three months old.

It is Amusing to notice that some original items which were published weeks ago in the MEDICAL RECORD, after going the usual rounds through our contemporaries' columns as anonymously appropriated matter, are ultimately quoted and credited to other journals by our New York neighbors, thus taking the longest way round to get the surest way home.

State Societies of the Northwest Pacific Coast.—The State society of Montana meets April 23d, the Washington in Tacoma in May, the Oregon society in Portland in June, and the Idaho society in Boise City in September.

Dr. Edwin A. Bowerman passed a recent civil-service examination at Albany, in which he attained the highest average, 95.3. He has been notified of his selection to fill the first vacancy as junior assistant physician in the New York State hospitals for the insane. Dr. Bowerman graduated with first honors from the College of Physicians and Surgeons of Baltimore in 1895.—*Medical News*.

The College of Physicians and Surgeons of Chicago has purchased an adjoining building for hospital purposes, thus affording ample clinical facilities for its students.

The Ohio Medical Law.—Dr. Charles A. L. Reed, of Cincinnati, has been selected by Governor Bushnell as one of the members of the new Ohio Board of Medical Registration and Examination. He is a good man in a place that needs him very much.

Asphyxia from Fæcal Vomiting during Etherization.—At the recent meeting of the Society of the Alumni of Bellevue Hospital (*New York Medical Journal*) several cases of death were reported as the result of inhalation of fæcal vomit. It was suggested that the best preventive for such an accident, especially in cases of strangulated hernia, was local anæsthesia.

Refused to Take the Oath.—A graduate of the Central Medical College of St. Joseph created quite a scene on commencement night, by refusing to take the Æsculapian oath upon being presented with his diploma. The audience, not understanding that the oath is not compulsory and supposing that the diploma would be withheld in consequence of his refusal, viewed the student in the light of a martyr, and expressions of sympathy were heard from every quarter.—*Medical Herald* (St. Joseph).

Quoting the Advertisement as an Article.—Some of our exchanges are already quoting one of the advertisements of the *MEDICAL RECORD* as if it had been an original article contributed to our columns.

Successful Operation on a Wen of the Scalp.—According to a report in a Western newspaper a bold and enterprising surgeon has succeeded without general anæsthesia in removing an encysted tumor of the scalp. We presume that the newly-discovered local pain destroyer, cocaine, was employed. When any operator shoulders such responsibilities without consultation he takes his reputation in his hands. With a thorough knowledge of anatomy, with ample preparations against possibly formidable hemorrhage, and with careful antiseptic precautions, patients may sometimes recover. The surgeon deserves congratulations accordingly. It is to be hoped that no accident occurred to the sac, that none of the larger vessels of the scalp was wounded, and that the important hair-bulbs in the vicinity escaped injury. At last accounts the patient was doing reasonably well, with no marked increase of temperature and in that happy frame of mind which is a hopeful reaction from a danger passed. These unusual cases are always of interest, and it is to be hoped that an authoritative statement, with such technical details as are beyond newspaper comprehension, may be published in some medical journal or be brought before some scientific association. Statistics of actual recovery are not always trustworthy unless accompanied with a detail of qualifying circumstances. The diagnosis was made without the use of the Roentgen rays.

Increase of Study in Germany and Decrease in Practice.—The German government proposes to increase the term of medical study by another year, making six in all. The last year is to be devoted wholly to clinical study. While thus increasing requirements for licensed practitioners, no effort is made to suppress quackery nor to protect regular medicine. Petitions for such protection have been voted down in the Reichstag. If the additional year is imposed it is not unlikely that many regular medical men will practise without government sanction, thus fighting the quacks on their

own grounds. According to our German correspondent the quacks have so much the best of it that they "ride in chaises," while the poor but respectable practitioner walks. "Here in Berlin," he continues, "the contrast between quackery and honest medicine is so apparent that the quacks make from twenty to thirty thousand marks a year, while more than half of all the Berlin physicians scarcely have an average yearly income of three thousand marks."

The Medical Club System in England is being discussed after a lively fashion by suffering medical men. The latest abuse appears to be the founding of a club dispensary by certain well-to-do people of a district and the hiring of a doctor at a small salary for the attending physician. This is even worse than our own dispensary system.

A Brooklyn Physician who was recently involved in an accusation of improper relationship with a patient whose husband was suing her for divorce, has succeeded in his efforts to have the case reopened. The testimony which implicated the attending physician, and which has seriously affected his practice it is claimed, was wholly false and without shadow of foundation. If this is shown on second trial to be the case, some amends should surely be made for the damage done an innocent man.

The American Climatological Association.—The thirteenth annual meeting of the American Climatological Association will be held at Lakewood, N. J., May 12th and 13th.

The New York Celtic Medical Society.—The regular monthly meeting of this society was held March 26th. The paper of the evening was on the "Treatment of Puerperal Septicæmia," by Dr. John Aspell.

Metropolitan Medical Society.—The regular meeting of the Metropolitan Medical Society was held March 24th. "The Treatment of Postural Deformities of the Trunk" was the title of the paper of the evening, by Dr. Jacob Teschner. He reported the results in seventeen cases treated up to the present time, of which fifteen were discharged cured and two very much improved. Of the fifteen cured cases all but one were rotary-lateral curvatures of the spine of different degrees of severity. The average time of treatment was about two and one-half months. He subjects his patients to two forms of exercise, viz., developmental and corrective. A series of twenty-six exercises for muscular development are executed with dumb-bells weighing from one-half to five pounds each. The corrective exercises are the following, with variations according to individual requirements, viz.: Swinging bells (weighing from five to forty pounds each) overhead from the floor, with the upper extremity rigidly extended. This is done first with one hand a certain number of times, and then the same number of times with the other hand. Then swinging a pair of bells with both upper extremities rigidly extended. A pair of bells (also weighing from five to forty pounds each)

are pushed alternately and automatically from the shoulder to above the patient's head, to the individual limit. Various exercises are also given with steel bars and bar bells weighing from twenty-six to over one hundred pounds. The rationale of these corrective exercises is that when a patient swings, pushes, or sustains a heavy weight above the head, the action of the back muscles to sustain the weight and equilibrium is such as to cause a curved spine to approximate a straight line. When a heavy bar is pushed with both hands the head is bent backward, the spine is straightened and hyperextended, and the faulty position is thereby corrected. The forcible and voluntary temporary reductions of deformity, frequently repeated, can, according to Dr. Teschner's results, be depended upon to cure any case of curvature or other postural deformity which is amenable to any form of active treatment. He takes the standpoint that (1) lack of strength and lack of muscular development, (2) habitual faulty position with superimposed weight, and (3) lack of co-ordinating power or lack of muscular control are the more potent etiological factors in producing deformities. He corrects deformities by reversing these conditions: (1) By developing the muscles and their strength; (2) by acquiring an habitually corrected position with superimposed weight; and (3) by educating all the muscles to proper co-ordination and complete control. All the patients improve in general health. Measurements and strength tests were made according to the Sargent system and recorded upon the Sargent charts. The chest capacities, chest depths, girths, breadths, and strength tests are generally increased, the abdominal depths are decreased, and the feet, the foundation of correct posture, are improved, inasmuch as all flat feet become shorter from the increase of the depth of the inner arch, and normal feet grow. The weight increases as a result of this treatment, and the general circulation is improved in that the pulse is less frequent as a rule and of better volume. Gymnasium and class work for deformities are strongly objected to. So are all supporting or immobilizing appliances, because they interfere with perfect muscular freedom. The development exercises and the corrective work were demonstrated by several of Dr. Teschner's patients. The paper was discussed by Drs. V. P. Gibney, A. M. Phelps, Lilienthal, Royal Whitman, A. G. Gerster, and Fred. Lange.

The American Academy of Medicine.—Preliminary "press notice" of the twenty-first annual session at Atlanta, Ga.: The twenty-first annual session of the American Academy of Medicine will be held in the "dancing hall" of the Hotel Aragon, Atlanta, Ga., on Saturday, May 2d, and Monday, May 4th. The academy will meet in executive session with closed doors on Saturday, May 2d, at 10 A.M. The open session for the reading of papers will begin at about 11 A.M.; there will be a recess for lunch from 1 to 2:30 P.M. The "reunion session" and annual dinner will be held on Saturday evening. An executive session will be held on Monday morning, after which the special discussion on "Methods of Medical Education" will be the order of the day. The Association of

American Medical Colleges and the Confederation of the State Boards of Medical Examiners and Licensers have accepted the invitation of the council and will participate in this discussion.

Selling Bodies for Dissection.—Captain White, the veteran keeper of the Bellevue Morgue, has been charged with selling bodies for dissection.

Medical Course Made Four Years.—Governor Morton has signed the new medical bill, which raises the medical-student course from three to four years, and allows students who entered colleges to graduate under the rules in force when they matriculated. This law applies to all the medical colleges in the State.

The Disputed Case of Leprosy.—Prof. George H. Fox has examined Long Tong, the Chinaman, and has pronounced him to be a leper. The patient has been transferred to North Brother's Island accordingly. In his report to the Health Department concerning the alleged contagiousness of leprosy, he says: "I can say positively that during all this time there never has been a single case of infection from one of these patients. The popular impression about leprosy and its contagious features is very erroneous. Leprosy is no more dangerous than consumption. Persons in a street car are very much more likely to contract tuberculosis from the expectoration of a consumptive than to get leprosy from the presence of a leper. Leprosy is, of course, contagious, and probably it can be contracted in accidental ways, as other diseases of the blood are; but the terror of a leper is something that is not founded on fact. Ten years ago a man in a very advanced stage of leprosy was treated here at one of the hospitals, and he recovered, proving that leprosy can be cured. There are other cases just as conclusive, but that man was carefully treated in the hospital, and he received all the comforts of life, whereas, if he had been locked up in a lazaretto and his food handed through a hole to him, probably he would have died. The great difficulty in curing leprosy is that as soon as a person learns he has it he is made to believe that all hope is gone. He is treated as a doomed man and made to believe that he is an object to be shunned by everybody. Naturally enough, it is difficult for a person to recover under such circumstances."

No Spitting in Street Cars.—Hereafter the following sign is to be posted in all the passenger cars of this city:

"HEALTH DEPARTMENT, NEW YORK CITY.

"Spitting on the floors of public conveyances is a nuisance, is frequently a means of communicating disease, and is hereby forbidden.

"By order of the Board of Health.

"CHARLES G. WILSON, *President*.

"EMMONS CLARK, *Secretary*."

President Wilson suggested that if the signs do not stop the practice, an ordinance be passed authorizing the company to call a policeman and have the offender put off whenever he violates the rule.

Clinical Department.

COMPOUND FRACTURE OF THYROID CARTILAGE.

By E. L. BELL, M.D.,

NORTH WOODSTOCK, N. H.,
FORMERLY SURGEON TO THE BOSTON EMERGENCY HOSPITAL.

ALTHOUGH accidents somewhat similar to the one here recorded may not be uncommon, this case seemed to me interesting, not only on account of the complicated nature of the injury, but also on account of the uninterrupted recovery under manifestly unfavorable circumstances.

J. K—, age twenty-nine years, cattleman, while loading a vessel was gored in the throat by a steer. He was brought to the Boston Emergency Hospital in an ambulance.

Examination disclosed an exceedingly large, dirty, lacerated wound, extending from the median line of the neck to the edge of the sheath of the large vessels of the neck on the right side. All the larger muscles covering the larynx and trachea were reduced to pulp, with the exception of a few remaining shreds. The two alæ of the thyroid cartilage were completely separated in the middle line. The right ala had a longitudinal fracture involving two-thirds of its surface. The cricothyroid membrane was ruptured and the cricoid cartilage was badly bruised. The trachea was opened throughout its whole extent almost down to the sternum. The thyroid body was apparently entirely destroyed.

Hemorrhage had at first been severe, but it was easily controlled by a temporary dressing. There was a large lacerated wound under the right ear, which was immediately closed with silkworm gut.

The patient was placed in the tracheotomy position. The anæsthetic used was cocaine in four-per-cent. solution. Under strict asepsis, with the assistance of Dr. W. B. Segur, I cleansed the entire region with a weak bichloride solution, removed the loose fragments of cartilage, trimmed the edges, fitted and fixed them in place with fine sterilized silk. The different shreds of muscles were next cleaned, patched, and fastened in proper places, as were also the tracheal rings. The fascia and skin were next sutured with silkworm gut and covered with simple antiseptic dressing.

Beyond passing reflex spasms of the glottis and some slight dyspnoea, the patient seemed to suffer no great inconvenience; but he was watched carefully for any signs of approaching œdema or septic pneumonia. The temperature the day after the accident was 100° F., and remained at this point or below during the man's stay in the ward. The wound was dressed on the third day. It then exuded a little dark blood on pressure. On the fifth day a slight discharge appeared which was found to come from a small sinus resulting from deep muscle-suture irritation. On the eighth day the external sutures were removed. Under daily dressings the discharge had seemed to lessen. On the twelfth day two silk muscle sutures sloughed out and were removed. On the sixteenth day the sinus was curetted under cocaine anæsthesia. The next day there was but little discharge, and in a week the wound had entirely cicatrized.

Step by step, beginning the day after the injury was received, the gradual change from almost complete aphonia to approximately perfect vocal action could be plainly marked. In fact, I am inclined to believe that if the patient's supply of stimulants during his convalescence could have been curtailed, the slight amount of huskiness present on his discharge would have been much less noticeable.

The plan of using a trachea tube and allowing the

surface to close in with more or less rapidity has been suggested, but it has seemed to me that the method followed in the instance above outlined, provided the case can be watched, is much quicker and easier both for patient and surgeon.

A WHISTLING LARYNX.

By CARL E. MUNGAR, M.D.,

VISITING SURGEON, WATERBURY HOSPITAL, WATERBURY, CONN.; ASSISTANT SURGEON, MANHATTAN EYE AND EAR HOSPITAL, THROAT DEPARTMENT, NEW YORK.

MISS FLORENCE W—, aged nineteen, with a larynx perfectly normal in appearance and function, can whistle at any time without the use of lips, tongue, pharynx, soft or hard palate, or cheeks. If the mouth is opened, the tongue pulled out and held firmly between the thumb and index finger, as is customary on inspecting the larynx, and a laryngeal mirror is held in position upon the soft palate, pressing it back against the posterior pharyngeal wall, the patient during exhalation can whistle very clearly and loudly enough to be heard in any part of a large room. The position of the vocal cords is as follows: There is close approximation of the vocal cords for their anterior three-fourths, while posteriorly there is left a triangular space, which is more or less encroached upon as high or low notes are produced; at the same time the ventricular bands are constantly changing their position, according as the note is high or low. This young lady says that her range is about one and one-half octaves. She further says that a cousin, a young boy, possesses this power of laryngeal whistling, but to a very limited degree, and that in her own case she has been able to whistle in this peculiar manner since childhood. The ordinary definition of "to whistle" is "to utter a kind of musical sound by forcing the breath through a small orifice formed by contracting the lips" ("Century Dictionary"); it must then be added that "to whistle" is as above but with this addition: "or make a musical sound by forcing the breath through a small orifice left by the partial approximation of the vocal cords, the only other anatomical aids being the ventricular bands."

The objection that this is not a whistle cannot hold, as a proficient singing-master has assured me that the sound is purely a whistle and not a singing or speaking note. This is, then, a unique case of the production of the whistle in the larynx unaided by the lips, tongue, cheeks, or palate.

WATERBURY, CONN.

TANNIN IN THE TREATMENT OF SUPPURATING SINUSES.

By M. A. VEEDER, M.D.,

LYONS, N. Y.

In looking over my notes of cases I find the following not heretofore reported which may be of interest. The patient undertook to vaccinate herself, using pus from a vaccination ulcer from which the scab had literally rotted off. The result was the formation of an abscess which followed the sheaths of the muscles of the upper arm to the shoulder and thence those of the pectoral muscles, extending beneath the breast and opening near the margin of the lower ribs. Sinuses were established opening on the interior and exterior surfaces of the arm, in the axilla, and on the lower part of the front of the chest. At this stage the case came under observation. Large quantities of thick creamy pus were being discharged through all the various openings, and a pocket containing perhaps half a pint of pus was evacuated by incision just be-

low the breast. The various sinuses and pockets formed a curiously entangled chain so underlying and surrounding important structures as to be difficult of access, especially in the axilla and at the side of the chest. It was found, however, that water could be made to traverse the entire tract with perfect freedom. So copious was the secretion that ordinary syringing was difficult and tiresome. A reservoir containing several gallons was therefore arranged, so that very copious douches could readily be given, and then work began. Plain water seemed to have but very little effect except temporarily, as it cleaned out the pus mechanically, the cavities refilling rapidly and the sinuses secreting freely throughout their entire course. The following agents were tried thoroughly one after another and alternately from one to another, and in all strengths that it seemed safe to use. Carbolic acid, bichloride of mercury, boric acid, permanganate of potash, peroxide of hydrogen, salicylic acid, salicylate of soda, and perhaps some others that I have forgotten. The constant douching was comfortable to the patient and appeared to have the effect of preventing any formation of new sinuses or cavities. This continued for several weeks with some improvement at times, the more superficial sinuses especially closing in part but not effectually. The case became very discouraging and tedious, and operation was suggested but not consented to. Finally the whole thing was cured, practically at a stroke, the agent employed being nothing more nor less than a strong solution of tannin. At first a moderately strong solution was tried in one of the sinuses in the arm; it acted so satisfactorily that its strength was increased until it was nearly a saturated solution and the entire tract of the cavity was filled with it. The immediate effect was to coagulate the pus into a cheesy mass, which, when squeezed, came out of the various openings in the form of long worms. All this material was simply washed out with plain water and there was no longer any purulent secretion whatever, a clear fluid only appearing, the sinuses and cavities healing very kindly and with great rapidity. The interior of the abscess cavity and sinuses, in short, was simply tanned. It is a line of treatment that was hit upon almost by accident. I do not know whether it has been used heretofore. In the peculiar case described it certainly was effectual.

FINAL HISTORY OF A CASE OF (SO-CALLED) MEMBRANOUS ENTERITIS.

By H. S. KILBOURNE, M.D.,

SURGEON U. S. ARMY,
FORT CLARK, TEX.

IN February and June, 1888, I reported in the MEDICAL RECORD a case of membranous enteritis. As this affection is somewhat rare and, in adults, mostly peculiar to women and of debatable pathology, the subsequent history and termination of my case may be entitled to record.

The patient was in the following year (1889), on account of his continued disability, retired from active service in the army, when he went to reside in the city of Portland, Ore. He remained there during that year and continued under my observation and advice, requiring and receiving but little medical treatment. The mucous casts were occasionally discharged, but there was no recurrence of the severe paroxysms described, although the slighter gastric disturbances persisted. His general health was much improved. In 1890-91 he changed his residence to Colorado Springs in that State, passing from observation. There, about a year subsequently, after a chill due to exposure in driving about the country, he died, rather

suddenly as was reported, from an intercurrent acute pulmonary disease. There was, so far as I could learn, no autopsy. Assuming what is probable, that the reproduction and discharge of casts persisted to the last, the duration of the disorder was about ten years (1882-91). Reviewing this case in the light of Butler's recent able contribution to the literature of the disease,¹ I have been impressed with its prominent neurotic manifestations and the absence of the characteristic symptoms of inflammation. The scant pathological records of cases point to the mucous follicles of the colon as the source of the casts and the seat of morbid action, and yet in typical cases gross anatomical lesions have been found wanting in them. The unstable nervous system, profound and persistent anæmia, and a complexus of gastric disorders were prominent and puzzling features of a case suggestively feminine in quality.

A CASE OF BRONCHO-PNEUMONIA WITH SECONDARY ACUTE MENINGITIS DEVELOPING ON THE THIRD DAY IN AN INFANT TWO MONTHS OLD—RECOVERY.

By CONRAD P. KORNREICH, M.D.,

NEW YORK.

D. M.—, male, aged two months, family history good; came under my care January 9, 1896. On examination there were areas of dulness all over the right lung, a short hacking cough, rapid and shallow breathing, rapid and feeble pulse, some cyanosis, and a temperature of $103\frac{1}{2}^{\circ}$ F. The usual treatment was prescribed, with persistent counterirritation over the chest in the form of mustard plasters. Stimulants in the form of strychnine and cognac were persistently administered. The child apparently responded to this form of treatment until the evening of the third day, when I was hurriedly summoned and informed by the mother that the child had just had a severe convulsion and vomited severely.

On inspecting the little one the pupils were seen to be considerably dilated; there was tenderness along the back of the neck; there was constant twitching of the muscles of the back of the head and neck, of the face, and of the arms. That night the child was very restless and apparently seemed to be in pain, for it tossed its little head about and constantly moaned, keeping this up for fully forty-eight hours.

The following morning photophobia and painful hearing had developed. I ordered ice bags to be continuously applied to the head, applied two leeches, one to each temple, and administered internally twentieth-grain calomel tablets every half-hour, bromides and chloral for the relief of the pain and restlessness. This treatment was adhered to for five days, after which the acute symptoms gradually subsided, with rapid and complete recovery resulting. This case is reported because of recovery following its occurrence in so young an infant.

95 ATTORNEY STREET.

Ipecacuanha in Bee Stings.—A paste of pulverized ipecac is said to be a valuable local application in bee stings.

Masters in Medicine are not lacking in France. *La Médecine Moderne* presents the portrait of one upon the title page of each issue, and this, too, in a journal which appears twice each week the whole year through. *Les maîtres de la médecine* are distinguished-appearing men—but oh, so numerous!

Stated Meeting, March 19, 1896.

DANIEL LEWIS, M.D., VICE-PRESIDENT, IN THE CHAIR.

Surgical Treatment of Harelip and Cleft Palate in Children.—DR. D. H. GOODWILLIE read the paper, which was illustrated by numerous diagrams, models, casts, and instruments. Harelip, he said, is the result of imperfect intrauterine development. The upper lip is developed from a central and two lateral points. When these points fail of union a fissure results. The fissure may be on one side or on both; it is rarely in the centre. It may be accompanied by fissure of the hard and soft palate. In correcting the deformity the bone lesion must be operated upon as early after the birth of the child as its condition and the circumstances will permit, and before ossification takes place to prevent moving the bones into normal position. He had operated as early as the twelfth hour after birth. This first important step in correcting the deformity is accomplished by mechanically forcing the maxillary and nasal bones into normal position and closing the harelip and soft palate. Before entering into the details of the operation, the author described the orbicularis oris and the muscles inserted into it and running out in various directions, particularly those in the upper lip. There was less change in these antagonistic muscles in infants than in adults showing harelip.

The bony framework having been restored, the further operation of closing the lip became not only simplified, but the result was better. It was his custom to follow the one step immediately by the other. Every divided fibre of the orbicularis oris must be joined to its fellow in order to restore its normal action and the force of the levator muscles inserted into it. This could be best accomplished by union in the centre of the lip, whether in single or double cleft, and he made his incisions accordingly by the removal of V-shaped pieces. He used special plates for holding the fibres of the orbicularis on both sides evenly, and inserted a pin through the soft parts down into the bone outward from the nose on each side, in order to prevent action of the antagonistic muscles inserted into the orbicularis. The mucous membrane and skin of the lip wound were united by catgut. The retaining-plates and pins held the parts until union had taken place. The wound was sealed with antiseptic collodion or rubber tissue. If the bone and soft tissue were not supported during union, some of the fibres of the orbicularis might give way and cause deformity.

In bad cases there was pouting out of the under lip. His method was to take out a section of the pouting mucous and submucous tissue down to the orbicularis and close the wound with catgut. In order to remove a symmetrical section, he used a lipgauge of his own devising.

After pointing out different varieties of cleft hard palate, he said all bone should be preserved, sacrificing only enough to freshen the edges when closing the parts. The operation should be done before the second month. Where the lip alone was involved, it should be done before the child began to speak, or at two years of age. In fissure of soft and hard palate the judgment of the surgeon would decide whether to close the former first or do both at one sitting. In his experience little cutting was required if one began soon after birth to stretch the muscle toward the septum from both sides. The child should be in good condition and the tissues should have thickness in order to se-

cure success. Nasal deformity might also exist and should receive attention. The septum might be absent; there might be hypertrophy of turbinated bones, even to the occlusion of the nares. In the further description of his mode of operating in different classes of cases, Dr. Goodwillie showed an instrument which served the double purpose of a tongue depressor and of a tube for administering chloroform. The spray of the anæsthetic playing from the upper surface of the depressor came directly in contact with the parts to be anæsthetized.

DR. ROBERT ABBE opened the discussion. No other operation so taxed the ingenuity of the surgeon as those upon the mouths and lips of infants. The beginner often had bad results by reason of his rashness. While he could see some advantage in certain of the instruments, he thought there was a greater display than was demanded in most cases. The method advised, of making a double harelip of a single one, cutting some of the lip away on the sound side in order to bring the two together to make a central scar, seemed to the speaker not at all necessary. Regarding fixing the lips by the plates, he asked if they did not leave a tender scar. He had found that any form of pin or suture transfixing the lip would produce a tender scar if left in longer than three or four days. This was fully as long as he left two in, one placed at each labio-nasal fold and fastened taut by adhesive plaster at the zygoma, the purpose being to maintain the broad muscular edges during primary union. In fissure of the hard palate, in some infants much could be done toward modelling the jaw. The fingers would often succeed without instruments. He had once thought that palate operations ought not to be done; that the defect should be filled with a plate fitted by a dentist. But such an apparatus was troublesome and expensive, and he had come to favor making repair by operation. Venous hemorrhage could be controlled by pressure. He made no effort to avoid dividing the palatine artery, as it would be likely to be cut anyway while separating the soft parts. The earlier one operated the better. He had obtained an excellent result in one case two days after birth. The soft parts tended to model the hard parts, hence the lip operation ought to be done early.

DR. B. F. CURTIS gave as other reasons for operating as early as possible the fact that the child was more easily nourished, it took the nipple better, and had a better chance of life because of greater attention given by the mother, who previous to the operation might have regarded the child's deformity with horror. There was also less danger of bronchitis on account of the gaping mouth. There were two dangers attending the operation on the palate—the length of the operation and hemorrhage. Therefore he followed the suggestion of Wolf, of first elevating or separating the muco-periosteum, not freshening the borders, packing in gauze and waiting five or six days, then completing the operation. The first part was attended by greatest loss of blood, and these young patients could afford to lose but little. The second part was the longer.

Dr. Curtis did not think it necessary to make a double harelip in operating, as practised by Dr. Goodwillie, and would attribute to removal of the extra amount of issue in the upper lip the eversion following in the lower lip. Regarding the retention plates, he thought they invited lodgment of milk and consequent sepsis. The tendency to-day was to do away with such instruments. Few men to-day used pins or wire, but sutured simply with silkworm gut or horse-hair. He thought the apparatus for giving chloroform would be very convenient.

The President, DR. LEWIS, asked whether the lower lip would not in time resume its normal shape without taking out a piece of mucous and submucous tissue.

DR. GOODWILLIE said the pins used in the old method of operating did produce a scar, but those inserted for fixation produced no scar which was noticeable. The operation on the lower lip was not resorted to except where there was much pouting.

SECTION ON GENERAL MEDICINE.

Stated Meeting, March 17, 1896.

REYNOLD W. WILCOX, M.D., CHAIRMAN.

Acute Bronchitis.—DR. WILLIAM H. THOMSON read a paper on this subject. The findings of pathological anatomy might be valuable in other respects, but they afforded little assistance in elucidating the etiology of acute bronchitis. Thus, a typical attack might be caused by getting the feet wet, by toxins in the blood, by epidemic influenza, yet in all of these the palpable changes were the same, consisting of initial hyperæmia, shedding of epithelia, engorgement, etc. The clinical incidents were suggestive as to the etiology. Mucous membranes did not take on inflammation simply because they were mucous membranes, for we observed inflammation of this lining of the bronchi and larynx frequently, while in the neighboring tract devoted to deglutition, and consequently much exposed, catarrhal inflammation seldom occurred. The inhalation of irritating particles in the inspired air did not cause bronchitis once where chill of the cutaneous surface caused it ten times. The progress of our knowledge of the etiology of local inflammations, showing them to depend so often upon specific bacterial infection, might incline us to extend it to inflammations of the bronchial mucous membrane. But there was one consideration strongly against the probability that acute bronchitis was often due to bacterial agency. It was that all observers from the time of Lister to the present day had found the inspired air free from micro-organisms by the time it reached the trachea. Although ordinarily the air contained many hundreds or thousands of germs, they were arrested by the vibrissæ or by the epithelium in the nose and were there destroyed. The bronchitis of influenza might, at first thought, appear to be due to direct contact of bacteria with the mucous membrane of the tubes, but there were so many symptoms produced by this disease that it was more probable that a toxin in the blood caused them and the bronchial inflammation. On the other hand, the mouth always contained millions of bacteria, and multitudes of them passed down the gullet with every act of swallowing, yet they did not cause inflammation of the mucous membrane with which they came in contact.

Bronchitis developed first in the bronchial tubes themselves only in local infections, such as tuberculosis, or in toxic conditions of the blood, as in gout. In all other cases, which constituted by far the greater number, the bronchial inflammation was by extension downward from the upper respiratory passages. In some instances the process seemed to attack the different divisions of the respiratory tract simultaneously, so that it might not be apparent in the nasal cavity first; but even in these cases one could see an intimate association of sensibility between the different parts of the respiratory tract which pointed strongly to a specific nervous connection between them, both sensory and motor, and which had a great deal to do with the genesis of catarrhal processes.

Bronchitis began so uniformly with sneezing, sore throat, cough, that both laity and the profession concurred in the statement that its origin was in catching a cold. But what was a cold? The anatomical definition of catarrhal inflammation required to be supplemented by the clinical phenomena. The sequence of

the clinical phenomena would indicate clearly a cutaneous area of origin. A chill of some portion of the surface, usually when wet, was so uniform that one not prejudiced in favor of the bacteriological origin of all diseases must regard it as causative. The exposure was usually of a limited portion of the body, seldom of the entire surface, for in the latter case there was usually a reaction with increased excretions and retention of health. The exposure of a few square inches of the back of the neck at an open car window would suffice to set up an acute attack of bronchitis; sitting in a room with wet feet would do the same, and the connection was as plain as that between green fruit and diarrhoea. But external chill produced different results according to the area exposed and the predisposition of the individual. There was commonly an intimate relation between the cutaneous area and the organs lying beneath, so that an impression upon the former would affect the circulation in the latter, notwithstanding absence of vascular connection between the two. In this way must be explained the arrest of vomiting by leeches placed over the epigastrium; the influence of cold on the præcordium on the action of the heart, etc.

Turning then to the accompaniments of such a catarrhal inflammation or cold, produced by exposure of a cutaneous area, we found swelling and pouring out of secretion. The effects of these varied according to the mucous membrane involved, being much more serious mechanically when in the bronchi than when in the pharynx. Liquid secretions were coughed up readily, as in hæmoptysis, while viscid secretions gave rise to much obstruction, pain, and coughing. When the inflammation reached the finer tubes, giving rise to so-called capillary bronchitis, the additional pathological processes which it caused and which often proved fatal depended chiefly upon mechanical obstruction. It was not different essentially from what was seen in extensive pneumonia dependent upon obstruction of a large bronchus, only in bronchitis the obstruction was in a multitude of tubules.

Against such occlusion nature had provided one watchful guardian, cough. The treatment of bronchitis resolved itself practically into the management of a cough. But cough was a motor outcome of excitation of a bulbar centre susceptible to a greater variety of afferent impressions than any other single nerve centre in the body. Thus, it might be excited by a disturbance within the cranium, as in basilar meningitis; by excitation of the temporal branch of the trigeminus, where hard wax accumulated in the ear; by teething, by uterine polyp, by pleuritis, etc. With all cases of bronchitis there was associated more or less of the purely irritant and useless cough. This could be and should be controlled, while the expectorant cough should be encouraged. The two could be differentiated by the fact that the irritant cough always consisted of separate sounds not linked together, like the blows of a hammer, while the expectorant cough invariably consisted of closely linked sounds, each successive cough being joined to the one which preceded it and the one which followed, like the links of a chain, and terminating with the secretion passing into the throat. He always listened to just how much there was of the purely irritant cough in bronchitis and sought to suppress it, while he encouraged the expectorant cough. The latter was attained by rendering the secretions fluid. One of the best agents was linseed oil in emulsion. The use of this was becoming so extensive that two firms had taken to manufacturing it under proprietary names, one of which had very generously offered him some stock. The irritant cough called for sedation, and this could be effected without weakening expectoration. Opium was the proper anodyne in all cases of inflammation, but it should be

given in the smallest possible dose in bronchitis. But the cough of irritability was as effectually and more safely controlled by chloral. When there were symptoms of tumefaction of the bronchial mucous membrane without secretion, he made counterirritation over the chest by pepper, a teaspoonful in a pint of boiling water, applied on cloths.

At the same time the dyspnea was quickly relieved by starting the secretion from the dry mucous membrane by giving teaspoonful doses of a solution of tartar emetic, one grain in a teacupful of water. Nauseating expectorants were not indicated unless in some cases of irritant bronchitis. In capillary bronchitis emetics were used to dislodge secretions. Here we must direct our efforts to maintaining the heart. Brief and quick applications of red-pepper infusion often aroused the flagging organ. The act of swallowing also caused cardiac stimulation. He saw no reason why we should not try to combat pulmonary collapse by gentle artificial respiration, and he had saved life by Sylvester's method.

A Bacteriological Cause Possible.—DR. ANDREW H. SMITH thought the truth in relation to the etiology of acute bronchitis might lie between the two extremes—it might require the combined influence of exposure and of germs. This would seem the more probable explanation where all the members of a family took a cold. The action of the cilia lining the bronchi was very necessary to the prevention of germs creeping along the surface, and he thought it likely that action was one of the first to be interfered with in bronchitis. That it was quite possible to inhale foreign particles was often illustrated by coal miners, those inhaling soot, etc., and who continued to cough up the black particles weeks after the last exposure. Under these conditions he had had opportunity to examine the lungs and had found the principal change and discoloration at the V division of the bronchial tubes, which sustained the chief impact of the column of air on its way into the dividing branches. Here was the point of irritation leading to cough. So long as the current proceeded with considerable velocity, it was capable of exercising this irritant action.

The reflex from the skin to the underlying organs was admirably shown by the shudder of the chest on throwing cold water on its surface, which did not occur when one dashed water on any other part of the body. The equalization of the temperature was largely maintained by the relation between skin and internal organs, the blood going to the interior during cold, to the skin during warmth. The very quick results obtained in bronchitis by giving a nauseating expectorant or by the inhalation of chloroform or steam went to confirm his belief in spasmodic contraction of the circular fibres of the bronchial tubes in addition to the tumefaction. He had found capsicum in vaseline, put up in tin-foil tubes, excellent for counterirritation. He wished again to lay stress on the importance of supporting the right heart in obstructive bronchitis, etc. Arterial dilators relieved the venous side of the circulatory apparatus.

Found no Germs in Simple Bronchitis.—DR. J. WINTERS BRANNAN said that at the Willard Parker Hospital they had found no germs in the bronchial tubes in simple bronchitis complicating fatal diphtheria. Germs, however, were always present in broncho-pneumonia cases. He was disposed to agree with Dr. Thomson regarding the etiology, that it was not bacterial.

He had met with a case of fibrinous bronchitis last summer, the woman having coughed up a complete cast of some of the bronchi. This was a very rare affection, and most patients were said to die from it, but this one recovered easily. She said she had had a similar attack ten years before, when Dr. Loomis had made the diagnosis. There was a dis-

pute among authors whether the cast was fibrin or mucus.

Regarding treatment he said that when connected with the Boston Dispensary he found linseed oil with syrup was the favorite prescription among patients receiving it. He now used flaxseed tea chiefly, and applied flaxseed poultice, one-fourth part mustard, to the chest when there was constriction. He employed tepid bath, change of position of the child, lifted the foot of the bed to encourage drainage toward the larger bronchi and pharynx, used codeine instead of opium, and gave muriate of ammonium and iodide of sodium.

The Alkaline Treatment.—DR. L. DUNCAN BULKLEY told how he was led to employ the alkaline treatment for the prevention or cure of colds, using sodium bicarbonate in fifteen to twenty grain doses. He had received many letters commending it since his article recently appeared in the MEDICAL RECORD.

Prophylaxis by Hardening.—DR. ACHILLES ROSE said he no longer had colds and was accustomed to jump into the river every day of the year, including winter. He did not recommend this to everybody, but thought that persons liable to take cold should harden themselves. He was once with a regiment of soldiers and among them colds were unknown, except on one occasion, when nearly all were affected, which went to show a miasmatic origin.

DR. BEVERLEY ROBINSON had found oxysulphuret of antimony less depressing and a better expectorant than a mixture of tartar emetic. He used it in broncho-pneumonia. He agreed with Dr. Smith that we should always have in view fatigue of the right heart as the main danger. One could not judge by the pulse alone nor by listening to the heart regarding the strength of the right side, but could obtain valuable information by observing the effects of stimulants on the circulation. Cardiac tonics and arterial dilators often gave more relief than anodynes under circumstances where many would administer the latter. Regarding alkalies, he thought that in many instances they were valuable in overcoming an underlying diathesis, but he would not have the profession receive this treatment as a panacea.

DR. THOMSON said, in some closing remarks, that oils had a special influence on mucous membranes, some on one, some on another, linseed oil acting more than others on the bronchial mucous membrane.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, March 16, 1896.

JOSEPH E. JANVRIN, M.D., PRESIDENT, IN THE CHAIR.

Obstetrics in General Literature.—DR. THEOPHILUS PARVIN, of Philadelphia, read a very interesting paper, characterized by literary excellence, reciting what he had found in general literature relating to obstetrics. In some introductory remarks he gave several reasons why doctors would find it advantageous to take rambles in general literature and imitate the style of non-medical writers. At the conclusion of the lecture a vote of thanks was extended unanimously to Dr. Parvin.

Syringing in Lachrymal Disease.—DR. WILLIAM H. BATES read a paper on syringing in acute and chronic lachrymal disease accompanied by complete or partial obstruction to the flow of tears through the punctum and duct leading to the nose. He employed for the purpose a glass syringe with a small rubber bulb on one end, the other end terminating with an opening not larger than a pin's head and having a little shoulder just back of the opening intended to fill the punctum and prevent return of the fluid. A glass syringe had several advantages over a metallic one. It was not affected by astringents, etc., and one could

see that the fluid was entering the duct. As a rule, water alone had given better results than astringents, antiseptic solutions, oils, etc. The injection should be continued until the fluid came away clear, sometimes requiring the use of a pint. In a number of cases cure or even improvement failed under injections made only two or three times a week, whereas daily repetitions were crowned with success. Chronic cases usually required months. Sometimes dilatation with a probe had first to be made, or incision through the strictured portion, but recurrence of the obstruction would be apt to take place unless the use of the probe were supplemented by syringing. Yet there were some cases in which the probe was sufficient.

The author's conclusions were: 1. Syringing is a valuable method in the treatment of lachrymal disease and should be tried in all cases. 2. Acute cases are often permanently cured by syringing. 3. Chronic cases are usually benefited and may be cured. 4. Cases which require operation and the use of probes may also need syringing to bring about a cure.

The Opprobrium of Oculists.—DR. H. S. OPPENHEIMER thought the paper touched upon a subject with which every specialist in diseases of the eyes must have had trouble, for it was the opprobrium of their specialty that many cases of lachrymal obstruction went away uncured. There was a great difference in the kinds of cases. Some patients would get well; some would get well rapidly; others were very rebellious. But he had never been able to cure one within two days, as stated by the author, and very few got well within two weeks. Cases in children could usually be cured, for they were seen earlier than those in adults. There was an inflamed mucous membrane with mucous, or possibly purulent, obstruction, and after syringing and cleansing acute cases got well. Disinfection was hardly possible, for all the germs and foreign particles coming in contact with the eyes were washed away by the tears. The cases and the treatment must differ—a fact which was self-evident to one who understood the anatomy of the parts, the function of the lids in relation to the punctum and the flow of the tears, and the pathological changes in the different cases. In nine out of ten of the chronic cases the trouble was at the nasal end of the duct; catarrh, etc., occluding the duct and calling for the use of the probe. In fact there was so much difference between the various cases that we could not speak of any one treatment. He regarded the syringe simply as cleansing. He employed one made of metal, such as dentists used for syringing cavities of teeth.

No One Mode of Treatment.—DR. NEIL J. HEPBURN thought all were agreed that syringing of any diseased cavity or canal so as to keep it clean was a long step in the process of cure, but, as Dr. Oppenheimer had just stated, after we had gotten through with all the syringing and opening of the sac, we had a large percentage of cases which did not recover, and he did not know whether the specialist got along much better with them than did the general practitioner. Cutting and probing versus syringing had been before the profession for discussion many years. He believed that most of the members used all the methods, one after another, either intelligently or at hazard, and had about the usual percentage of recoveries. At least, the patients disappeared from observation. The main difficulty was in getting rid of the strictured part. As in genito-urinary surgery, some of the strictures got better and remained better, while some required periodic treatment. Very little violence in relieving one stricture might give rise to another.

DR. FRIDENBERG thought syringing had been largely abandoned. The paper could be considered an attempt to revive it. He hardly thought it would prove successful. The reader had only shown more patience

in carrying out the treatment than most could. It was very difficult to induce patients to come to an office every day for months in order to have it applied. It was simply a valuable adjunct in certain cases. Probably in ninety per cent. the lachrymation had been caused or aggravated by ectopion or some error in refraction. The correction of any error in refraction was absolutely necessary.

DR. GALLANT thought the experience of the author was in line with that of general surgeons, tending to the abandonment of disinfectants for sterile water. Where one used only a little warm water it produced a congestive effect, whereas long-continued irrigation produced contraction of the tissues and opened the canal.

DR. BATES said he had attempted to show the value of syringing in connection with probing in stricture of the nasal duct, and after much experience he could state positively that a cure could be effected, not to be followed by recurrence. The object of syringing was not alone to wash out blood clot after operation, but also to prevent congestion which otherwise would be produced by passing the probe. In preventing congestion he prevented formation of stricture.

Therapeutic Hints.

Syphilis Antitoxin.—The immunity of syphilitic subjects against new infection is due to the antitoxin in their blood. The serum of a subject of secondary syphilis seems the most active. The quantity to inject varies from one-half to five cubic centimetres. It is recommended to military surgeons who can keep their patients long under observation.—COTTERELL, *Méd. Mod.*, No. 82, 1895.

Diarrhœa, as well as cutaneous eruptions, may result from the use of iodide of potassium. Though free iodine, iodates, or other impurities may be the cause in cheap brands of the drug, the same results may follow the use of the purest article.—MONTGOMERY, *Medical News*.

Thyroid Extract fails in psoriasis, scleroderma, and acromegaly, and probably acts only upon the subcutaneous tissues.—UNNA.

Eczema.—Electrostatic treatment is applicable to all forms of eczema, the moist form being more rapidly improved than the dry. Treatment is more rapidly effective in children than in adults. In all cases treated the different patches did not return if electrostatic treatment had been continued long enough.—BORDIER, *Arch. d'Elect. Méd.*, February 15, 1896.

Hot Steam has been employed by Liberson in chronic eczema with good results. It aids in the absorption of superficial and deep infiltrations, diminishes or arrests purulent secretions, removes crusts, checks oozing, and provokes a regeneration of healthy tissues. The duration of the *séance* is from a quarter to a half hour. In obstinate cases it has given good results.—*La Méd. Mod.*, February 15, 1896.

Theobromine should be classed with the functional epithelial diuretics which are inoffensive for the kidneys. The length of time of activity is shorter than for digitalis. It is indicated in dropsies of cardiac origin and also in those of Bright's. It is prescribed in a daily dose of from three to five grains for a period of four days only. Wafers of fifty centigrams each are prescribed, of which eight are to be taken the first day, six the second and third days, and four the last day of the course. In small doses it may be con-

tinued as a tonic for several weeks, especially when combined with phosphate of sodium.

R Theobromine,
Neutral phosphate of sodium. 10-20 gm.
For forty wafers. One at beginning of each meal.
—HUCHARD, *Gaz. des Hôp.*, February 22, 1896,

Hysterical Hæmoptysis in men is not at all influenced by ergot, ice, astringents, etc. Treat the neurosis. Good results follow hypnotism. In one patient thus treated the attacks, from being of daily occurrence, became first weekly and then semi-monthly.—LAURENT, *L'Indépendance Méd.*, No. 6, 1896.

Acute Gastro-Enteritis of Children.—Bismuth is especially efficacious when combined with Colombo:

R Colombo rad. 1 gm.
Make an infusion with water. 75 "
Filter and add:
Bismuthi subnit. 3 "
Syr. aurant. cort. amar. 15 "
M. S. Teaspoonful every two hours.

—TRABAUDT, *La Presse Méd.*, No. 67, 1895.

Tincture of Cantharides has been recommended in albuminuria by Du Cazal (*Gaz. Hebdomad. de Méd. et de Chir.*, No. 43, 1895). An average of twelve drops was administered during the twenty-four hours. Cure was obtained with surprising rapidity in four out of five cases, and the fifth was greatly improved. Three instances were of unknown cause or due to cold, and the other two were of scarlatinal origin.

Hiccough persisting for three days in a non-hysterical girl was cured by spontaneous tongue traction. The affection appeared to depend upon disease of the stomach. It was noted that while the tongue was being examined the hiccough ceased. The girl was then advised to protrude her tongue in a regular rhythmical manner. The cure was explained as due to reflex action upon the bulbar respiratory centre.—LÉPINE, *Le Bul. Méd.*, No. 13, 1896.

Emulsion of Castor Oil.—Pour fifteen to twenty grams of the oil into a glass of milk and heat while stirring. In a few minutes a perfect emulsion is obtained. This can be sweetened with orange-flower syrup. A smaller dose given in this way acts as well as a larger dose of the pure oil.—KLEIN, *Journal d'Accouchements*, January 26, 1896.

Odontodol is a preparation known in Italy for its superiority as an antiodontalgic. It has the following composition:

R Hydrochlorate of cocaine. 1 gm.
Essence of lauro-cerasus. 1 "
Tincture of arnica. 10 "
Liquid acetate of ammonia. 20 "

Place in the hollow tooth a tampon of cotton wet with the solution. A crystal of pure carbolic acid placed in the carious cavity usually suffices, however, to relieve the pain of toothache.—*Journal d'Accouchements*, January 26, 1896.

Lupus Erythematosus, when superficial and after removal of scales with soap, may be treated with sulphate of zinc and sulphuret of potassium, each thirty grains: rose water, three and one-half ounces; alcohol, three drachms. Apply lightly by means of a sponge for from five to twenty minutes, allowing sediment to adhere to the surface.—DUHRING.

Inversion.—In asphyxia suspend the infant head downward, grasp the feet in the right hand, and support the shoulders on the palm of the left. If no quick result follows, perform artificial respiration by flexing the thighs on the abdomen.—MANLEY.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ARMY SERVICE VERSUS PARLIAMENTARY QUESTIONS—NOTIFICATION—ISOLATION—THE ELECTION TO THE MEDICAL COUNCIL—PHARMACOLOGY—ANNUAL MEETING OF THE MEDICO-CHIRURGICAL SOCIETY—DR. DUDLEY'S OPERATION—THE SCHOOLBOARD QUESTION—ACTION AGAINST THE BRITISH MEDICAL JOURNAL.

LONDON, March 6, 1896.

THE government was questioned in the House as to the ominous fact that there was no competition at the last examination for the army medical service. In fact the War Office obtained only nine eligible candidates for seventeen vacancies. This is what has come of snubbing the medical service, and politicians would be well advised to redress the grievances and meet the demands of the department. The army medical service might easily be made so attractive as to secure the pick of young surgeons, but with the prejudices of Lord Wolseley and others it is difficult for gentlemen to be found to fill up vacancies—and the difficulty increases and will continue to do so until the officials learn manners.

Some complaints are also made about the method of marking adopted at recent examinations. This may very likely be again altered, as it does not affect the petty prejudices of the so-called "combatants;" but whether reverting to the old mode of marking will do much good is a doubtful question.

Irish members further pressed the government respecting the alleged falling off of Irish candidates for the medical service of the army, and broadly insinuated that it was because there did not happen to be a representative of the Irish colleges on the examining board. The government reply was that the subject was under the consideration of the secretary of state and it was hoped to make a statement on the matter when the army estimates were introduced.

The extent to which the notification of diseases has been adopted by our local authorities, according to an official statement in the House of Commons, is greater than has been generally supposed. The act of 1889 is now in force over districts containing above twenty-seven millions of inhabitants. The question of making that act compulsory has been raised, but, with so much progress voluntarily, the advocates of the scheme may well rest satisfied.

Measles does not require notification, and just now some medical officers are seriously exercised as to what is to be done to restrain its ravages. Isolation among the poor is impracticable, and hospitals do not exist which would accommodate the cases.

The proverbial disunion of Irish human nature seems to extend to the medical element. With a degree of ingratitude disgraceful even to political cliques the Irish Poor Law doctors have deserted their one advocate, Dr. Jacob, who has given a quarter of a century's labor to their cause. With voting-papers sent to them ready-stamped they have not taken the trouble to fill up, sign, and post them—*i.e.*, about a quarter of the voters have neglected to poll, and that in spite of energetic appeals by the several candidates. The consequence is that the Medical Council will have another representative of corporate interests. But the council is already burdened with too many advocates of vested interests. It was to secure independent members that direct representation was granted, and this election once more shows the weakness of that scheme. In this case, too, a rivalry was started between the provinces and the capital—a rivalry

similar to that so often fostered for other purposes by the British Medical Association. What good can be expected from such absurd divisions while principles are unheeded and union neglected? No wonder that politicians treat our wishes with contempt. They know we are too divided for our support to be worth bidding for.

A good deal of discontent has been manifested at the rather frequent revision of the curriculum. The dissatisfaction has culminated in an outburst of wrath against the College of Physicians for voting to remove the word pharmacology from the subjects of examination. The anger is not widespread, but is rather confined to a few who have been posing as pharmacologists and have succeeded to some extent in imposing a restricted meaning on that word of wide import. It almost looks as if some lecturers had been fascinated by the word and only wanted to substitute it for the expressive phrase, "materia medica and therapeutics." Some of these gentlemen, however, declare that pharmacology means physiological action; others suggest that it includes medicinal action—in short there is much confusion among those who delight in using the word. Some of them despise materia medica and declare it consists in "spotting specimens"—a most inadequate description. Others dilate on the position of pharmacy—others, again, on the art of prescribing. Now, all these things were once recognized as included in the course and the lecturer on materia medica and general therapeutics had a free hand, and could vary his instructions with the wants of his class and the more or less prominence given to parts of the subject at different periods. "Professor of Pharmacology" may have an attraction to some minds, but from a student's point of view all the recent talk is of little moment. The word may appear or not in his curriculum, but the substance of the former designation will remain and he may be assured he will not escape examination in materia medica and therapeutics at one or more points, and the examination will assuredly include pharmacology, whatever be the meaning attached to the word. The syllabus should guide both the student and teacher, while it should also restrain examiners, especially those who profess to be pharmacologists.

The annual meeting of the Royal Medico-Chirurgical Society was held on Monday, when Mr. Hutchinson, the retiring president, delivered an address and invested his successor, Dr. Howship Dickinson, with the insignia of office. In his address Mr. Hutchinson, according to custom, alluded to the fellows who had died during the year. He said the new regulations had worked well and the three special discussions had increased the usefulness of the society and induced a larger attendance of the fellows. Of special discussions of our premier society I have sent you such full reports that your readers will be able to appreciate the work which so commends itself to the retiring president.

At the last meeting of the Gynaecological Society Dr. George Keith advocated operating for antelexion by the method of Dr. Dudley, of Chicago, and related four cases. When he first heard of the plan he did not think it would do any good, but he changed his mind after seeing Dr. Dudley's results. Mr. Skene Keith confessed that when his brother drew his attention to the operation he did not think it would answer, but having seen it succeed he had performed it about twenty times.

Dr. Bantock and Dr. Godson testified to the value of the plan of dilatation which has been so successful, but Dr. Keith thought that a single operation which would effect a cure at once was preferable to repeated dilatations, especially in the case of virgins.

The adjourned meeting of medical men respecting the action of the School Board was held yesterday.

It was resolved that pending an alteration of the system, certificates should not be supplied to children attending the board schools.

An action for libel against the editor of the *British Medical Journal* has resulted in a verdict for £150. The action arose from remarks in the ethical department of the journal, which, I fancy, most members of the association would consider justifiable. One must not doubt the wisdom of a jury, but perhaps we may question that of the plaintiff.

BLOOD-LETTING IN PNEUMONIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: To Dr. Mercer's able article with the above title in your issue of February 29th, kindly allow me to add my little experience with free bleeding in the congestive stage of this terrible disease, together with a few remarks.

Having practised for several years in the heart of the anthracite coal regions, whose population consists to a large extent of Poles and Hungarians, I have had ample opportunity to test the merits and demerits of venesection in acute pulmonary congestion.

These people, as is well known, make periodical visits to the physician for the purpose of being bled—fifty cents and from one to one and one-half pints of blood are about the limit. Bleeding is almost a religion with them, so strong is their faith in it.

The miner, by reason of his occupation and the great variations of temperature—the mine and surface temperatures—under which he labors, is at all times a fairly good candidate for an attack of pneumonia, a disease which he fears almost instinctively and for which he seeks advice immediately. I have been repeatedly summoned to attend these poor unfortunates, and found them suffering in the first stage of pneumonia; sometimes I have been called as early as an hour after the premonitory chill. Very often they would not ask what was the matter—they seemed to know this without being told—but would bare the arm and tell me to bleed.

Having been educated at a school where blood-letting for this disease was heartily condemned, but in the same breath advocated in the early stages of eclampsia and apoplexy, I was somewhat timid and loath to cast aside the teachings of the time—the teachings which appeared to me the sheet anchors of successful and scientific treatment. There was no help for it, however; I had to bleed. Then came one of those sudden awakenings, the almost startling realization that my teachings were somewhat dogmatic and incorrect, that bleeding was a big success objectively and subjectively.

The miner who, before being bled, was laboring under difficult, painful, and quickened breathing; frequent, tight, and spasmodic cough; full, bounding, and accelerated pulse; flushed and anxious countenance and a rapidly rising temperature, would confess, after being bled, to feeling much better—and he looked it to a degree.

The pulse and respiration ratio harmonized with the patient's confessed improvement, the heart became less irritable and worked more smoothly and with more ease, arterial tension was much lessened, nervous excitement was much reduced, the pain was almost or entirely gone, breathing was easier, cough improved, the face not so flushed and anxious. This improvement was invariable when I bled in the congestive stage.

On several occasions I have bled twice in the same patient, with marked benefit each time.

Arterial sedation has never accomplished this for me and I scarcely think for any one else.

I have, several times, bled in the second stage with more or less benefit, but not with so much success as in the congestive stage.

The plea "sthenic subject" cannot be advanced here. The miner with his clogged-up lungs, chronic bronchitis, and emphysema, is far removed from this category.

Bleeding relieves to a marked extent all the symptoms of congestion of the lungs, not because the patient is sthenic or asthenic, but because it relieves the congestion. Dr. Mercer has proved this by quoting several well-known examples. The blood in this disease is highly coagulable, and the slightest obstruction will, of course, favor coagulation; by bleeding the obstruction is lessened or removed and the fluidity of the blood is promoted (a very necessary indication), and this may be further encouraged by the free use of the ammonium salts.

So convinced and enthusiastic am I of the relief afforded by free bleeding in the early stage of pneumonia and its tendency to make the disease run a milder course, that, should I or mine be stricken with the disease, I would resort to it promptly and boldly.

Pneumonia is the same disease, no matter who has it. The nature of the soil and the previous health of the individual decide the severity of the attack.

In a strong, healthy, robust man with good heart and lungs, and lots of pure, fresh air to breathe, it will almost always present its milder side, and for very palpable reasons his heart and lungs are equal to the emergency, his nervous system is too well fortified; they are proof against being, at least immediately, overwhelmed by the poison; they may be temporarily embarrassed, but that is all; their natural resistance is too great and the disease gets the worst of the argument.

It is not so with the poor, debilitated sweat-shop candidate of city life; his heart and lungs quickly give out under the sudden and terrible strain to which they are put; his nervous system is but poorly fortified to withstand the deadly invasion, and just as often he succumbs.

The miner occupies, in my opinion, a place midway between these two extremes, inclined to some extent toward the latter category. His heart, often hypertrophied by reason of his arduous labors and the extra force necessary to propel the blood through the sclerosed patches in the lungs, is, consequently, unfitted to have an extra burden thrust upon it. His lungs, filled with foreign matter, perhaps with patches impervious to air, should offer an excellent stamping-ground to the diplococcus and other pneumobacilli. But do they?

With such a condition of the pulmonary tissue, together with the altered and pathological state of the whole respiratory system, I have often wondered how these poor men ever escaped without pneumonia, pleurisy, or phthisis pulmonalis. That by far the largest majority do escape these diseases is a well-known fact and difficult to account for.

Perhaps the irritative particles cause the giant cells of the animal economy to become focussed at the point of irritation, to be present in great numbers, and on the *qui vive* for all invading microbes; or perhaps these carbon particles exercise a germicidal influence upon the invaders. Pulmonary tuberculous phthisis is, considering all things, not frequent among these people.

In conjunction with my late much-lamented friend, Dr. D. Gumpert, of Wilkes Barre, Pa., I have made frequent examinations of the sputum in what would be considered favorable cases, but have never succeeded in finding the tubercle bacilli.

I do not and cannot claim any originality in observation or remarks; they are no doubt time-worn, oft-

repeated, and gray. I therefore offer these observations somewhat timidly and with much hesitation, being prompted only by the high regard in which I hold timely venesection in acute pulmonary congestion and by the great relief which it affords to the suffering patient.

I hope this much-deserving subject will receive consideration and discussion by those more capable and having greater opportunities than myself.

M. GOLTMAN, C.M., M.D.

MEMPHIS, TENN.

WOMEN PHYSICIANS IN THE STATE HOSPITALS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The failure of the New York Civil Service Commission to find suitable candidates for the position of women physicians in the State hospitals heretofore, and the complete failure to find candidates at all at the last examination advertised in January, deserve discussion.

The evolution of the doctor has not been an easy development in the last decade. The MEDICAL RECORD truly says that he must "show knowledge and skill or else acknowledge that the problem is too great for him." Among women, trained nurses have been developed from the latter class—while the former has been left to cope with the immense amount of mental and physical work now required in the medical schools.

It is not from fear of the civil-service examination at Albany, nor from inability to pass it, that applications failed to be made. Students entering medical schools usually have either the degree of A.B. or the certificate of a high school. The Regents' report shows that at the last examination the graduates of the Woman's Medical College of the New York Infirmary stood at the head of the list, those of the College of Physicians and Surgeons holding the second place. The women applicants from other States showed equal scholarship, and most of the women's medical colleges have extended the time allotted to the course of study to four years.

The lack of applicants for the place of assistant women physician in the New York State hospitals, is chiefly owing to the three years of medical practice required before the civil-service list can be entered. Other considerations are the low salary without yearly increase and the lack of opportunity for general practice. If I am correct, an assistant physician has the right to compete for a superintendent's place after five years' service. Few physicians of either sex desire to make a specialty of mental diseases, and only those who do would care for the posts in question. The two hard examinations—one competitive—after three years' practice, ought to be a bar, unless for a specialty. No one engaged in active professional work can afford to give much time to preparing for examinations.

The annual salary of \$1,000 may seem large to the ordinary, careless reader, and would, no doubt, be really sufficient to secure applicants, if application could be made immediately after the State University examination giving the right to practise, or even after six months' post-graduate study in addition. The training given by our eastern colleges is such that a graduate would be capable of acting as assistant under a competent superintendent. But a young doctor who has been in practice for three years is fairly started in the profession, is beginning to earn something, and cannot be expected to give up what has just been gained for a subordinate post in an insane asylum.

The demand made by the State law is a separate question. There is no room for doubt that, wherever women are confined for any cause whatever, competent and educated women should be vested with authority.

The omission of the word "insane" in the advertisements has been misleading. A man who advertised for "a teacher" would probably get no answers, but if he advertised for a teacher of French or of mathematics he would have plenty of answers. The expression "State Hospital for the Insane" would attract the few young doctors wishing to make a special study of insanity.

There ought to be more public advertising of vacancies and examinations, and such advertising ought to be more definite and explicit.

E. J. CHAPIN MINARD, A.M., M.D.

BROOKLYN, N. Y.

ENLARGE THE LUNACY COMMISSION AND MAKE IT MORE REPRESENTATIVE AND MORE EFFICIENT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The MEDICAL RECORD's excellent criticisms of the bill now before the legislature, providing for a further increase of the powers and prerogatives of the State Lunacy Commission, will, I trust, enlighten the profession and also open the languid eyes of the easy-going public as to the true nature, the political animus, and the dangerous possibilities of that commission as we observe its workings to-day.

Such a commission, so constituted, so selected, and so endowed with arbitrary powers, was never before heard of, either in American or in British history.

Our State Lunacy Commission was originally designed, like its British model, to be simply an advisory board. It was imagined that here, as in England and Scotland, its members would be men selected for their integrity, their peculiar fitness and experience in all humane methods, and their high standing in the community, who should represent the best element in society and stand as a protective barrier against abuses of every kind in the State care of the insane. Such was the hope at the start, and though the selection of the individuals constituting the commission was much criticised, still the public was willing to wait and give the incongruous trio a chance to test their fibre and prove their fitness for the humane task which they seemed so eager to undertake. We have now waited for five years—and they have proved years of disappointment. Year by year these commissioners have pushed themselves into place and power, assuming one prerogative after another, laying out details of work which they could never hope to accomplish, raising their salaries, extending their jurisdiction, grabbing after appropriations, crowding the legitimate asylum trustees to the wall and assuming their functions, replacing some superintendents with others more pliant, and at length controlling the entire asylum appropriations of the State, amounting to millions of dollars and compelling the expenditure of this vast sum to pass through their own hands, subject only to their own caprice. Thus the authority of the local boards of trustees is nullified and the judgment and experience of years set at naught.

Meanwhile the public remains indifferent, trusting that all is right, and the newspapers are made to ring with praises of the commissioners' beneficent work, with stories of economies practised, the people's money saved, and the angelic benevolence which governs the commission in its humane and self-sacrificing labors.

What the public needs is a little more knowledge of the facts. They need to know more of the inner workings of this commission of three, and to realize that it may easily grow into a political machine with possibilities of a dangerous sort.

Your excellent proposition to increase the number

of commissioners and allow each asylum district to be represented on the State board is plainly the first step to be taken in the direction of a safe reform. Three men, however carefully selected for their fitness and their activity, can never perform the service which the State demands in this vitally important field. Three archangels even could not do it and do it well. There is safety and efficiency only in a full representation of every district and corner of the State. Men of high character can easily be found who will serve without salary, simply their travelling expenses being paid; and by a systematic division of the labor the visitation and inspection of asylums can be thoroughly and also cheaply accomplished, and every safeguard maintained.

The time is ripe for a reorganization and reform, and the profession and the public will heartily sustain you in your outspoken protest against the present system and in your efforts for a wholesome change.

MEDICUS.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 21, 1896:

	Cases.	Deaths.
Tuberculosis.....	155	138
Typhus fever.....	2	0
Typhoid fever.....	10	2
Scarlet fever.....	136	5
Cerebro-spinal meningitis.....	2	4
Measles.....	424	25
Diphtheria.....	196	25

Slobbering.—Dr. Sanchez de Silvera (*Lo Sperimentale*) asserts that healthy infants never dribble. The latter condition is due either to disorders of the digestive apparatus or to obstruction of nasal respiration, but is altogether unconnected with dentition.

Arrest of Hemorrhage in Estlander's Operation for Removal of Portions of Ribs.—Mr. C. Hamilton Whiteford (*Lancet*, March 7th) gives the following sensible directions: "After exposure of the thoracic wall to be removed the intercostal arteries are compressed by ligatures on each side of the pieces of ribs to be removed. An aneurism needle is passed unthreaded from the middle of one intercostal space, entering the pleural cavity, to the space above, and brought out close to the upper border of the rib above. The needle is then threaded and withdrawn. This ligature when tied contains below the rib a bunch of intercostal muscle, which acts as a plug in the intercostal groove, thereby obliterating the vessels. The entire thickness of the chest wall between the two rows of ligatures is then removed close up to the ligatures, the bleeding being confined to the divided ribs, where time is no object; periosteal flaps covering in the cut ends of rib tend to prevent subsequent necrosis, probably due to infection of the bone by the pus from within, which I have seen occur in several cases. The ligatures should be of material which is easily absorbed to prevent the possible necessity of future removal."

Dirt-Eating Children.—Dr. John Thomson gives notes of eleven cases which illustrate in a tolerably characteristic way the clinical history which is generally obtained in cases of this morbid condition. In some cases only one or two abnormal things were eaten; in many almost anything within reach was swallowed; and it seems that the variety of unnatural

substances craved is much more limited in cachectic cases than in those beginning in young babies. Children suffering from pica for some time have a peculiar look about the face. Their complexion is dull and unhealthy, and they are often hollow eyed with a hungry and unhappy look.

In these cases in which the children were allowed to indulge their craving to any great extent there were always some diarrhoea and occasionally obstruction from impaction of hard bodies in the rectum. In none of these cases was the patient ever seriously ill as the result of the habit, but instances have been recorded which have ended fatally. It was interesting to notice that in cases where the habit was formed in early infancy, and where the patient was some time under observation, the craving ceased about the age of three years. This seems probably connected with the growth of the child's intelligence and the widening of its interests.

The nature and etiology of pica constitute a very difficult question; but it seems natural to class such cases as a minor psychosis, along with such "bad habits" as sucking of the thumb and fingers or of the tongue, masturbation in little children, and the rocking to and fro (without implication of the genital organs) in which some young children find pleasure.

Treatment is only to a very small extent a matter of medicine. It must aim at the modification of any conditions which favor the continuance of the habit. The indications are mainly four: 1. Keep the child away from the substances for which he has a morbid craving. All habits are strengthened by practice, and their hold slackens under disuse. 2. Improve the condition of the digestion. It seems more than likely that local uneasiness often plays some part in the etiology. 3. Improve the general health. It is to the weakly that such cravings come, and the strong readily throw them off. 4. If possible, change the child's surroundings and take his mind up with new things, and let him be kept busy and happy.—*Pediatrics*.

A Death Certificate.—The following unique document was presented to the authorities not long ago, upon the death of a United States pensioner: "I do further state that the one cause and real cause of death was from the effects of his old trouble, Chronic Rheumatism, hastened by an attack of Lagrippe which he in his weakened state had not the strength or vital life to resist. He was gradually growing weaker, slowly dying, from the old chronic trouble, and the sudden attack of Lagrippe produced congestion and death came more quickly than otherwise would have been the cause; although it was a known fact that he was gradually dying and death would have surely resulted within a short time. Thus Chronic Rheumatism was the real cause of death, hastened by a severe attack of Lagrippe which caused congestion of the lungs, and for want of vital life and power to act the Arterial system ceased motion. The breath of life could not pass into the lungs; the lungs congested, filled with venous blood, and life was gone. By the loss of vital life and inherent weakness of the powers of nerve tissue, I mean for want of strength and life. The arterial system ceased motion and the breath of life could not pass into the lungs, that in connection with the spinal cord it could not connect the sensation of life longer to the vital nerve tissue, called animal life of man. Therefore it is plain that Lagrippe alone would not have proved fatal in this case had not — been already in a weakened debilitated condition throughout his whole system from the effect of the chronic trouble of long standing, and his gradually approaching death was hastened by a severe cold and an attack of Lagrippe, which otherwise would not have had a fatal termination."

Cuba as a Breeder of Pestilence.—That present sanitary conditions in Cuba render the island a menace to the United States is asserted by Dr. George T. Maxwell in *The Sanitarian*, February, 1896. He says that Spain's interest in Cuba, aside from the sentimental idea of retaining her colonial possessions intact, is simply and entirely sordid. It is with Spain a question of revenue of dollars and cents simply. The welfare and happiness of her subjects are secondary to that, and in consequence the health conditions of Cuba give her little or no concern; but to the inhabitants of this country the importance of this latter question cannot be overestimated. Cuba, because of her proximity and commercial relations, is regarded as the point of danger to the Union, as it relates to that bugbear of modern times—yellow fever. Millions of dollars have been spent in efforts to prevent its intrusion into the States. While his knowledge of that disease—its history and nature—forbids assent to the commonly accepted notion that it is contagious, he is in complete accord with those who hold that its persistent prevalence in Cuba is attributable to the utter disregard of the simplest principles of hygiene. That it is due to local unsanitary conditions in Havana and Rio Janeiro has been declared with great emphasis by men whose official position, if nothing else, will give the weight of authority to their dicta.

Well and Happy when She had Enough.—We once knew a woman, an inmate of a county infirmary, who attained the ripe age of one hundred and six years, who had always been an inveterate user of tobacco, which owing to her poverty was a luxury not easily obtained. To economize in its use, she first chewed the plug and dried the quids, from which she made a tea and drank of it freely, then the residue was carefully redried for consumption in her T. D. pipe. The old lady proudly affirmed that she had never been ill.—*Cleveland Medical Gazette*.

A Remedy for Black Eye.—There is nothing to compare with the tincture or strong infusion of capsicum annuum mixed with an equal bulk of mucilage or gum arabic with the addition of a few drops of glycerin. This should be painted over the bruised surface with a camel's-hair pencil and allowed to dry on, a second or third coating being applied as soon as the first is dry. If this is done as soon as the injury is inflicted, it will invariably prevent blackening of the bruised tissue. The same remedy has no equal in rheumatic sore or stiff neck.—*Medical Progress*.

What is Natural Labor?—Dr. Robert R. Rentoul (*British Medical Journal*) finds fault with the loose construction put upon the term "natural labor" in laws regulating the practice of midwifery nurses. He proposes the following definition: "Labor, at the ninth calendar month in a woman free from organic and functional disease of the heart, lungs, kidneys, brain, and other internal organs, and from all fever diseases; when there is no impediment in the maternal passage of either soft or hard nature to the passage of the child; when there is only one child in the womb; when the vertex of the child alone presents in either the first or second occipito-anterior position; when labor is completed within twelve hours from the commencement of labor; when a living child is born; when neither instrumental nor manual operations have been required; when the afterbirth comes away without the use of manual operation within twenty minutes after the birth of the child; when there is no laceration of any portion of the parturient structures; and when the mother does not die within thirty-one days after confinement; and when there is no puerperal fever."

MIDDLETON-GOLDSMITH LECTURES¹ — ON THE RELATIONSHIP BETWEEN INFLAMMATION AND SUNDRY FORMS OF FIBROSIS.

Continued from page 400.

By J. GEORGE ADAMI, M.A., M.D. CAMB.,

PROFESSOR OF PATHOLOGY, M'GILL UNIVERSITY, MONTREAL.

Lecture II., Part I.

IN my last lecture, having laid down my definition of inflammation—namely, that it is the series of changes constituting the local attempt at repair of injury or referred injury to a part—I proceeded to discuss the forms of fibrous hyperplasia which in the terms of this definition might well be held to be of inflammatory origin, and showed or attempted to show that such forms might be divided into the two main classes of productive and replacement fibrosis. Following upon this, I discussed the group of localized neoplastic fibrous hyperplasias, and pointed out that two groups might be recognized: the neoplasms of inflammatory origin and those of as yet undetermined causation—the true fibromata.

A consideration of neoplastic growth leads almost insensibly to the inquiry whether it is requisite that injury should precede new connective-tissue formation. The answer must, I think, be an unhesitating No.

In the nobler tissues of the body we know full well that increased work leads to hypertrophy or, more correctly, to hyperplasia; that is to say, a physiological stimulus leads to multiplication of the cell elements. What are the exact steps whereby this is brought about must perhaps always remain a matter of supposition, the most that we can say being that the call for increased work is followed by increased blood flow to the part with presumably increased nutrition, and that the increased work necessitates greater activity and increased metabolism in the individual cells. In connection with the basal connective tissue of the body it is difficult to grasp the idea of active work; to attempt to formulate such an idea may perhaps justly lay me open to the charge of dealing in transcendental pathology, and yet, as I shall proceed to show, a consideration of several forms of fibrous-tissue hyperplasia in connection with the different organs and diverse in character, forms in which it is difficult to decide any clear inflammatory origin, leads to the conclusion that there is a certain bond of union between them, that in them the existence of an increased strain upon the tissue is to be recognized, and that if we could group them together as being of the nature of "functional" hyperplasias or hyperplasias of increased function, we should advance materially in our grasp and comprehension of the same.

I had at one time thought that increased nutrition would be sufficient to explain these cases, and indeed I have been inclined to press this point until quite recently. It is certainly true (as is best shown by the cases of dystrophic sclerosis already mentioned) that a nu-

trition insufficient for the nobler elements of an organ suffices often for the active growth of connective tissue. This fact that a nutrition ample and suitable for one tissue does not suffice for another has long attracted attention, while the converse, or rather the corollary, was proved more than a century ago by John Hunter in his classical experiment of grafting the scantily-nourished cock's spur upon the cock's comb, and in this richly vascular and well-nourished area obtaining a remarkable, if temporary, hypertrophy of the grafted organ. Under certain conditions, then, active increase of nutrition of a part may lead to hyperplasia of its cells. Where the specific cells of a tissue undergo atrophy it may well be that there results a definite increase in the amount of nutritive fluid at the disposal of the baser interstitial cells, and that this has to be taken into consideration as well as any more direct stimulus to proliferation afforded by the products of tissue degeneration.

If this be so we are met with the likelihood that in conditions tending to altered nutrition of a part—leading to the tissues becoming bathed with lymph, either in excess of the needs of the specific and nobler cells of that tissue or of a quality not suited for the uses of those cells—there may be induced an overgrowth of connective tissue, a fibrosis, to be ascribed primarily to nutritional disturbances; or, in other words, it becomes likely that there may be nutritional fibroses as distinguished from inflammatory. Plausible as this seems, a fuller study of those cases which at first appear to be examples of simple nutritional fibrous overgrowth leads to the conviction that there is some further factor also at work. Or otherwise, increased nutrition, even if long-continued, does not inevitably lead to increased connective-tissue overgrowth, and therefore when we find this factor most in evidence in the production of any form of fibrosis we are bound to assume that there must be some additional directive factor. What I mean will best be shown by a study of the cases I am about to bring before you.

Take in the first place chronic obstruction to the flow of lymph. Where such obtains—whether by pressure of tumors upon the main lymph channels of a part, by blocking of the same, or by diseased states of the lymph glands—it is a matter of frequent observation that in the absence of satisfactory collateral tracts the part becomes swollen and gradually the fluid swelling gives place to a generalized, if not very extreme, connective-tissue overgrowth. In such cases the circulation of the blood through the affected area is maintained, there are no positive signs of inflammation evident either macroscopically or microscopically. We cannot recognize in the condition an attempt at repair. The primary injury has been at a distance from the region of fibrosis. Nevertheless, it may be argued that the stagnating lymph acts in these cases as an irritant to the connective-tissue cells and that the condition must be regarded as a productive inflammatory fibrosis.

While this view deserves full consideration, its acceptance must lead us almost inevitably to a point at which we become bound to regard as of inflammatory origin every condition of fibroid overgrowth, whatever be the stimulus. Some limit, I think, must be given

¹ Delivered before the New York Pathological Society.

to our conception of what is included in the process. It will be seen that thus far every example given by me until the present case has been strictly within the limits of the definition laid down, namely, it has been reparative in its tendency and has been due to evident injury to the part which becomes the seat of the fibroid change. We must, I take it, decline to consider a lesion as an inflammatory fibrosis in the development of which these two conditions cannot be clearly recognized.

Failing inflammatory origin, can we regard the example given above as being brought about by perverted nutrition pure and simple? I am inclined to think that we cannot. We should expect perverted nutrition to tell first upon other and higher tissues, but in many of these cases we find singularly little evidence of primary degeneration of nobler tissues (the muscles and skin of an affected extremity, for example). Where the circulation of healthy blood persists through such a region there must occur constant interchange between blood and lymph, and the blood must carry away the products of tissue change to a considerable extent. In deed we know that it is capable of vicariously removing much of the lymphatic fluid. With our present knowledge, all that it is absolutely safe to say is that we are here dealing with a quantitative disturbance in the lymph of the region, coupled with a mechanical disturbance, namely, increased extravascular and interstitial pressure; or, to put it otherwise, the cells of the connective tissue are subjected to an altered tension. The qualitative disturbance is of doubtful extent.

With these cases of obstructed lymph flow in a part certain examples of elephantiasis Arabum would appear to be classed—provisionally. So little has been accomplished in establishing the real nature of this disease, or more truly of this group of diseases, that the most I dare venture to say is that disturbed outflow of lymph from the affected region seems to be in operation in some cases (elephantiasis lymphangiectatica), while others present indications of venous disturbance (elephantiasis telangiectodes); others again (the neuromatous and lipomatous forms) can only safely be described as hypertrophic conditions approaching peculiarly close to generalized neoplastic formation.

Without discussing further the intimate nature of the fibrous hyperplasia in these cases at the present time, let me pass on to consider another class of cases. Increased bathing of the tissue with lymph and increased lymph tension may also result from active and from passive hyperamia. From either of these causes there may be passage outward of lymph from the blood-vessels in amount exceeding the efferent capacity of the lymphatics. Here again mere increased amount of lymph does not seem to lead necessarily to fibrosis. Some other factor or factors must be invoked. Thus in the liver, while extreme congestion leads especially to dilatation of the vessels with pressure atrophy of the specific cells, and though presumably there is here increased exudation, we get little evidence of fibrosis; long-continued moderate congestion induces, on the other hand, a very evident fibrosis, most marked, it is true, in the walls of and immediately around the intralobular branches of the hepatic vein, but seen also in the interstitial substance of the neighborhood. The peculiar arrangement of the new fibrous tissue shows that it cannot be regarded simply as an example of replacement fibrosis. The history in these cases points to the long-continued action of two factors—increased effusion of a not greatly altered lymph and long-continued (and probably varying) pressure affecting especially the central parts of the lobule.

The relative rarity and the slight extent of the fibrous hyperplasia accompanying well-marked passive

congestion is in itself an indication that the quality of the effused lymph plays a part in the development of the hyperplasia. Neither increased amount of lymph of poor quality in a part nor increased interstitial tension alone, it would seem, is capable of inducing overgrowth.

From this brief and hasty consideration of fibroid changes associated with the lymphatic and venous systems which are not to be regarded as of inflammatory origin, I will now pass on to discuss in somewhat greater detail what appear to me to be allied conditions affecting the heart and arterial system.

In ordinary practice apart from malformations, neoplasms, and the direct effects of trauma, the pathological changes of the heart valves are divided into the two broad classes of acute and chronic endocarditis, and although the non-committal name of arterio-sclerosis is in frequent use and although its employment appears to indicate a doubt as to the exact etiology of the condition, it must, I think, be admitted that such arterio-sclerotic changes are regarded as inflammatory in character, while sporadically the attempt is made to explain them by suggesting or presupposing the existence of some irritant substance in the blood which by direct action upon the vessel walls leads to injury and to reaction in the shape of connective-tissue overgrowth. I see, for example, that in a recent number of the *British Medical Journal* the apostle of uric acid, Dr. Haig, suggests that a cause for sclerosis of the heart valves is to be found in the irritant action of his beloved uric-acid crystals.¹

The existence of inflammation as a cause of sclerosis is more frequently to be determined in connection with the heart valves than with the arterial intima. Thus, it is well recognized that acute valvular disease may be followed by chronic thickening of one or more segments, that similar thickening may follow rupture of a segment, and that a valvule which has from any cause become injured, whether from simple roughening of its surface or more usually from the development upon it of vegetations, may by friction induce inflammatory disturbances in the parts with which it comes into contact.

In general these forms present an irregular or varicose type of fibrosis, but it is often difficult, if not impossible, to distinguish from them sundry cases of chronic generalized thickening in which through degeneration localized disturbances have occurred in the thickened valves with, it may be, ulceration, deposit of fibrin, and subsequent organization. There are, that is to say, doubtful cases in which it is practically impossible to declare whether we are dealing with processes following upon localized valve lesions or with the sequelæ of a generalized lesion.

Apart from these undoubtedly the most common form of valve lesion met with in the post-mortem theatre is a generalized thickening. Perhaps generalized is not a wholly correct designation, for in the slightest forms it manifests itself more especially along the edges of the mitral segments, and in the aortic valvules it is below the line of apposition, and again at the insertion of each segment, that the fibrosis is most marked. So common is the condition that in general we disregard it and, accepting it as almost physiological, make no note thereof. But in the examination of a series of hearts we may pass almost imperceptibly from one case to another until we reach conditions of extreme mitral stenosis, with such extensive generalized thickening of the whole valve and consequent shortening of the new connective tissue laid down that the mitral veil becomes converted into a circular plate, or more generally into a short blunt

¹ Alexander Haig: "Arthritis and Endocarditis Due to Drugs which Diminish the Solvent Power of the Blood for Uric Acid," *British Medical Journal*, December 28, 1895.

funnel with button-hole passage. And we come across case after case of this category which shows no sign of localized valvular disturbance either old or recent. The condition affects the whole of the valve and affects also the chordæ tendineæ, which are thickened and shortened.

While in acute endocarditis and in the nodose or verrucose sclerosis following upon such we find clear evidence of vascularization of the valves, and sections show fairly frequent vessels, this is not the case in the generalized thickening here referred to. The essential characteristic as revealed in sections is the rarity of the vessels; the fibrous tissue is laid down in layers parallel to the surface, and the most recent, the most cellular layers are those nearest to the endothelium—while the deepest layers, those most remote from the surface, show a peculiar tendency to degenerative changes. This tendency to hyaline swelling, fatty degeneration, and other evidences of necrobiosis—in short, to atheroma—is in itself a demonstration of lack of due vascularization and of malnutrition. Indeed, although I know that Luschka and others have described vessels throughout the extent of the mitral valve segments, my own injections of healthy hearts of several species have led me to the more generally accepted conclusion that the outer two-thirds of the mitral are almost, of the aortic valves are quite non-vascular, and to the further conclusion that healthy valves gain their nutrition in the main from the blood circulating within the heart. It is, I hold, by passage or circulation of the plasma through the stomata of the lining endothelial cells into the lymph spaces between the layers of connective tissue forming the supporting frame of each normal valvule that the main nutrition of the non-vascular areas of the valves is effected. While a layer of the vascular myocardium is contained in the proximal third or so of the segments, the outer two-thirds is scarce anything but a fold of the endocardium.

That the endocardium of the heart in general gains its nourishment from the blood within the chambers

ing endarteritis. The only and the obvious explanation why these peripheral fibres remain is that they have gained their nourishment through the endocardium.

Wherever we find well-marked vascularization of the outer two-thirds of the mitral valve, for example, we may feel assured that there has been inflammation present. The vascularization is strictly comparable to that obtaining in the cornea and other non-vascular areas, and indicates a development secondary to acute disturbance of the organ. In the generalized thickening to which I have referred one is struck by the peculiar rarity or almost complete absence of vessels and by the fact that the hypertrophic fibroid tissue is laid down after the plan of the normal connective layers of the region. And while obviously the new growth is continuing and the newest tissue is situated immediately beneath the endothelium, we do not there recognize any characteristic presence of small round cells. The appearances in this region are those of an orderly hypertrophy.

Two hypotheses may be adduced to explain this state of affairs: Either that the sclerosis is of inflammatory origin, the result of an irritant mild in character, causing little reaction but acting continuously over a long period, or that it is non-inflammatory and comparable to the fibroses already referred to in connection with the lymphatic system.

It is, I must frankly confess, impossible to adduce sufficient proof to entirely refute the former hypothesis—there may be chronic intoxications, auto-intoxications, or otherwise, due to substances which manifest a special tendency to act upon the endocardium; but such substances have not yet been isolated. Increased pressure upon the valves may directly damage them and the fibrosis may be the indication of a reaction to chronic injury, but the thickening would appear to be progressive and to continue until a condition is reached out of all proportion to the injury. We find, therefore, no absolute and sufficient reason for regarding the condition as of inflammatory origin. Nevertheless, the mere fact that we at present are ignorant of any immediate cause for the production of this lesion is not sufficient ground for flatly denying the existence of such cause, and even the fact that the microscopic appearances are not those of ordinary inflammation is not proof positive that the process which has led to the lesion has not been essentially of an inflammatory nature.

I cannot, that is to say, hold it proved or disproved that generalized sclerosis of the cardiac valves is in all cases of inflammatory nature. And the matter being thus an open one, it may be well to hold it possible that the second alternative may be correct and to seek for evidence in support of it.

Now, it is interesting to note that just those conditions in which there is a liability for the production of generalized thickening of the heart valves are clinically conditions in which there is found heightened arterial tension, conditions which also bring about arterio-sclerosis. It is just in these conditions that we might expect to have, with increased pressure, increased nutrition of the endocardium and of the intima—increased passage of plasma from the intracardiac blood through the endothelium, or perhaps, more correctly, between the endothelial cells. And I cannot but consider that this increased nutrition coupled with increased strain may afford a satisfactory explanation for this condition of so-called chronic endocarditis. Such a proof as one would desire of the correctness of this opinion is difficult if not impossible to devise, for the condition is the production not of a few hours but, not to exaggerate, of many weeks. Experiments upon the subject are almost if not quite outside the range of experimental pathology. Yet certain considerations appear to support

FIG. 1.—Transverse section of a papillary muscle exhibiting dystrophic sclerosis to show zone of intact muscle fibres immediately beneath the endocardium. *a*, Layer of intact muscle fibres beneath endocardium; *b*, sclerotic areas—replacement of atrophied muscle tissue by fibrous tissue. In this are venules and occasional atrophied muscle fibres; *c*, arterioles cut transversely, exhibiting thickened and sclerotic coats, and surrounded by intact muscle fibres; *d*, periarterial sclerosis.

and that the nourishing plasma may even extend for some little distance beyond, is very prettily shown in some cases of advanced sclerosis of the papillary muscles, which present complete fibroid metamorphosis of the central area of the pillars with a zone of healthy fibres all around the periphery immediately beneath the endocardium. These healthy fibres present no accompanying arteries; all the arterioles coursing up the papillary muscle may exhibit advanced proliferat-

the view. Roy and I,¹ for example, found that by constricting the first part of the aorta in the dog and in the rabbit and thereby raising the blood pressure within the heart, we were able in the course of a few minutes to bring about the production of numerous small pearly vesicles along the edges of apposition of the mitral and aortic valves, and we could only account for this development by assuming that with the increased blood pressure the plasma of the blood had been driven into the substance of the valve, and that the pearly vesicles of lymph (or plasma) appeared where they did because at these regions the difference between the pressure on one side of the valve segments and on the other was most in evidence. We obtained, so we held, clear proof that with increased blood pressure increased fluid penetrates the valve substance. It is important to note that similar pearly elevations are generally regarded as the first indication of valve disease.

But, as I have already pointed out, it is unsafe to regard increased nutrition alone as a cause of connective-tissue hypertrophy, and if we cast round to find what other factor there may be I am inclined to consider that it may briefly be entitled increased strain or tension acting upon the individual connective-tissue cells.

The idea may at first appear transcendental; we are not accustomed to think of the connective-tissue framework of the organism as being strained or, to carry this view to its logical conclusion, performing work. We only regard the nobler tissues as workers—the muscle fibres, the nerve cells and the specific cells of the glands. Nevertheless, we acknowledge freely that increased work thrown upon one of the connective tissues—namely, bone—does lead to its hypertrophy. It is a matter of common observation that not only are the bones of those accustomed to active exercise larger and heavier than the bones of the sedentary, but also that where any muscles are strongly developed there bony ridges and bony overgrowths are most developed at their origins and insertions.

The factors leading to this overgrowth may be summed up under the comprehensive title of increased work. And in connection with connective tissue where there is any force in action tending to draw apart and pull upon the constituents of the tissue—whether the force acts from without or (as in cases of increased effusion of lymph) from within the tissue—where, in short, there is a strain upon the components of the tissue—there, if we regard the work of the connective tissues, as is most plausible, as being to bind together and support other tissues, undoubtedly that work is increased and, granting that at the same time the nutrition remains good, we have a condition favorable to increased growth. *A fortiori* we might expect such hypertrophy where simultaneously the amount of nutrition is increased.

I suggest this very tentatively, for I have a horror of far-fetched pathology and an accompanying belief that the fuller our knowledge of a subject the simpler and more straightforward do we find the laws governing the associated phenomena, and it is only because the idea is straightforward and is in harmony with our knowledge of occurrences in connection with other tissues that I venture to formulate it. My aim in these lectures is throughout not to dictate but to suggest and call attention to the many diverse conditions which may bear a part in the production of increased fibrous tissue. At most I will here urge that it is possible that increased functional activity of the connective tissues results under favorable conditions in increased growth of the same.

[To be continued.]

TREATMENT OF FRACTURE OF THE PATELLA WITH CONTINUOUS EXTENSION AND WITHOUT CONFINEMENT TO BED.¹

By JOSEPH D. BRYANT, M.D.,

NEW YORK.

It is not my intention to call to notice anything essentially new, nor to make any portentous claims of the great benefit to be derived from giving heed to what may now be said regarding the subject of this paper. However, it is the intention of the writer to renew suggestions already made by him some time since bearing on the question of personal comfort and the proper physical status of patients who are suffering from fracture of the patella, and who for any reason are regarded as improper subjects for operative procedures or for continuous confinement in bed.

About three years ago this method of treatment of fracture of the patella was presented to the attention of the profession by the writer, along with a statement of the results in nine cases thus treated. Since that time several additional cases have been added to the record. It appears to me that I can do no better now than to describe again the method of application of the apparatus. In doing so, the verbiage of the previous description will be employed very largely, indeed—amended, of course, here and there by suggestions and modifications that are the legitimate product of a greater experience. The application of the mechanism can be properly divided into four steps:

First Step (Fig. 1).—This step consists in the application to the leg of a plaster-of-Paris splint extending from the bases of the toes up to and partly surrounding the lower fragment of the patella (3, Fig. 1). The plaster casing is applied closely to the leg

FIG. 1.—1, Plaster-of-Paris splint applied to leg; 2, upper part of splint resting against lower fragment 3; 3, lower fragment and line of fracture.

FIG. 2.—1, 1, Extension applied to thigh; 2, 2, front view of extension straps; 3, fractured patella; 4, 4, rubber extension.

at a time sufficiently in advance of the succeeding steps to permit of its becoming thoroughly hardened. The upper and anterior border is carefully shaped so as to hold the lower fragment of the patella in proper position.

The functions of this splint are threefold: (1) It affords ample protection to the foot of the patient from the effects of the pressure of the rubber extension

¹ Roy and Adami: "On Failure of the Heart from Overstrain," *British Medical Journal*, December 15, 1888.

¹ Read before the Practitioners' Society, February 7, 1896.

which passes across the sole from side to side. Practically the extension acts on the tissues of the thigh from the sole of the foot. (2) It confines the lower fragment in position at the outset and it is maintained there by the upward pressure of the splint, due to the force of the elastic extension as it passes across the sole of the foot (Figs. 1 and 4). In any event, the pressure of the splint at this point can be easily regulated, either by cutting away or padding it at the border contiguous to the lower fragment. (3) It gives proper support to the lower extremity of the extending-brace of the apparatus (Fig. 4).

Second Step (Fig. 2).—The measures of the second step are quite as strongly expressed by the illustration depicting it as words can define them. It consists in the application to the thigh of an adhesive plaster extension fashioned after the manner of the well-known Bucks extension, which in this instance reaches from the perineum to the upper border of the upper fragment (Fig. 2, 1, 1). The adhesive-plaster element of the Bucks extension is at that time held in place by the application of an ordinary roller, as usual. The plaster terminates in the form of loops at either side of the limb a little below the knee. The rubber extending-cords are passed through the loops (Fig. 2, 4, 4) or attached to hooks connected with them (Fig. 3, 4, 4). Moderate extension is then made on the loops by the elastic cords, to draw downward as far as proper the superficial soft parts of the thigh and the upper fragment of the patella. While extension is thus being made, the thigh is encased in a plaster-of-Paris splint reaching from the upper limit of the adhesive plaster down to the upper fragment (Fig. 3, 1, 1), where it is so fashioned and padded as to hold this fragment as nearly in contact with its fellow as possible.

FIG. 3.—Front View of Extension. FIG. 4.—Side View of Complete Apparatus.

The objects of this plaster-of-Paris addendum are: First, to aid in holding the adhesive dressing of the thigh in as firm position as necessary; second, to afford a support for the upper end of the posterior extending-brace already mentioned; third, to coaptate the tissues of the thigh, thereby exercising a controlling influence over muscular contraction; fourth, the making of direct extension on the quadriceps extensor, by reason of the close application of the splint to the upper fragment of the fracture and the tissues contiguous to it.

Third Step.—This step consists in placing the posterior support or brace in proper position and fixing

it there by means of plaster-of-Paris rollers carried around it and around the upper and lower segments of the splint where they lie in contact with each other (Fig. 4). These bandages should harden quickly, and thus incorporate the posterior support at the upper and lower ends firmly with the plaster-of-Paris structure at these situations (Fig. 4, 2, 2). A strip of wood about two inches in width, an inch and a half in thickness, and of sufficient length to be firmly incorporated in the plaster-of-Paris segments of the apparatus, will answer the purposes of the posterior support (Fig. 4, 4). Two small iron rods of proper length, placed parallel with and close to each other, will meet the demands of a support.

Fourth Step.—This step consists in drawing together the fragments of the patella as firmly as possible, either with adhesive strips obliquely applied, as is commonly done for this purpose, or the attainment of the object by means of a knee cap suitably constructed and applied to meet the same ends. If strips of adhesive plaster be employed, they are fashioned in place by attaching them to the uncovered parts of the posterior support (Fig. 4, 4). If the knee cap be used instead, it is applied without reference to this support. In applying the plaster strips at the line of junction of the fragments, care should be taken or the strips will be drawn between the fragments and thus interpose an obvious obstacle to proper repair. The hamstring tendons should be properly padded, so that neither the adhesive strips, the knee cap, nor the leather collars of the text-books can cause pressure or chafing of them. And, too, either of the above agents can be more readily and serviceably applied if the extending force be drawn aside to permit of greater room and more careful application. After the apparatus is comfortably in position, the patient is permitted to walk about with the aid of crutches, the limb meanwhile being supported in an advanced position by the agency of a sling carried beneath the sole of the foot and around the neck of the patient.

The apparatus should be made as light as is consistent with proper strength and service. In fact, it is not always necessary to embed the posterior support in the plaster of Paris by the addition of more of this material; but, instead, the posterior support may be bound in position by a firm roller bandage applied at either extremity of that structure. The adhesive plaster strips aid also in holding the posterior support in position.

I will not detain you by narrating the various changes that can be made in the utilization of individual elements of the apparatus, as these will be apparent as the circumstances suggesting them shall appear. Thus far thirteen cases of fracture of the patella have been treated under my observation by this method. The results from the treatment are equal in all respects to those obtained by other mechanical non-operative measures. The plan is presented not as a substitute for operative measures, but as an adjunct to them, as the patient can, with this appliance, be about without special danger or discomfort after wiring, etc., and closure of the wounds of the soft parts. The idea is to accomplish without long confinement in bed a cure that is equal to one ordinarily attained only by the sacrifices incident to such a confinement.

Gout.—Dr. Bishop (*Medical News*) says migraine is one of the commonest nervous manifestations of gout in its recurrent form. Neuralgia of the sciatic, intercostal, and fifth nerves, and rarely of other nerves, is often gouty in origin. Gouty subjects are liable to neuralgic pains in almost any part of the body. A true neuritis, particularly of the sciatic nerve, is not uncommon in such subjects.

A SYNOPSIS OF THE MODERN TREATMENT OF CHRONIC CARDIAC DISEASES.¹

By WILLIAM H. McENROE, M.D.,

NEW YORK.

WHEN any of the valves of the heart are injured by disease their natural mechanism is impaired; the force of the cardiac contractions is not thoroughly utilized and, as the result, enlargement or hypertrophy of the muscular structure of the heart takes place. There is much more in the diagnosis of heart disease than what is found as the result of physical examination. It must be remembered that some persons have inherent weak hearts, while in others the heart is large and powerful and contains a great amount of muscular resistance, which enables them to undergo the greatest fatigue without any apparent failure. This explains why it is that a valvular lesion in one person will be progressive from the start and run a rapidly fatal course, while in another case it will remain stationary for an indefinite period, being completely compensated by muscular hypertrophy. There are two forms of cardiac failure—one from overexertion of the muscle itself, the other from inherent inability. Of the former there is failure from chronic valvular or arterial disease; of the latter there are many cases where there is no hypertrophy or dilatation and the failure of the heart is due to simple deficient innervation. In many cases the heart instead of failing at once commences with weakness indicated by irritability, causing palpitation—for example, in hysterical persons, with dyspepsia there is often palpitation without any murmur or valvular disease, and this is undoubtedly due to deficient power of the heart caused by paralysis of its inhibitory mechanism. The strength of the heart is shown not by its rapid action, but, on the contrary, by its ability to restrain itself from beating too fast in conditions of nervous excitement or great emotion. In a perfectly healthy person the heart does its work without any consciousness of its existence except after violent effort. Very severe muscular exertion causes the heart to beat violently, and its action is distinctly felt. This excited action, however, is more readily induced in some persons than in others. It is not always an indication of disease and is often caused by disorders of digestion. Palpitation is found where the muscular power of the heart is deficient and cannot respond to the demands made upon it; here it is associated with dilatation and is readily induced by slight exertion. It is also found in lithæmia or gout and in chronic Bright's disease. It is a frequent symptom of Graves' disease or exophthalmic goitre, with enlargement of the thyroid gland and great nervousness, causing a rapid action of the heart and throbbing of the arteries all over the body. When hypertrophy is developed as a compensatory measure, palpitation is comparatively rare; on the other hand, when hypertrophy does not produce complete compensation then palpitation is readily induced with irregularity or intermittency of the heart's action. Palpitation results from the action on the heart of such substances as alcohol, tobacco, coffee, tea, etc.

Cardiac Hypertrophy and Dilatation may be produced by increased work of the heart or by increased pressure inside the heart or by weakness of the myocardium. The whole heart, or only portions of it, may be involved. Hypertrophy is caused by a thickening of the walls of the heart, by an increase in their muscular tissue. By dilatation is meant a condition of the heart with enlargement of its cavities, and marked diminution of its muscular power. The differential diagnosis is never difficult. In hypertrophy the first

sound is loud and booming in character, greatly intensified and accompanied by a heaving impulse against the chest walls. It may or may not be accompanied by a murmur. The intercostal spaces are widened, the apex is displaced downward, and its impulse against the chest wall is localized and distinctly visible. In dilatation the character of the first sound is totally different. It is short and valvular and somewhat resembles the second sound. The impulse is diffused, covers a large space, and the apex of maximum intensity may not be found, or it may be seen but cannot be felt. The pulse in hypertrophy is regular and full. If arterial sclerosis is present, then the pulse is greatly modified. The pulse of dilatation is weak, irregular, and generally rapid. The prognosis in hypertrophy is generally good, while in dilatation it is quite the reverse, and as the dilatation increases the prognosis becomes more and more grave. Cardiac hypertrophy is found in lithæmia or gout and is here associated with arterial sclerosis and accompanied by the pulse of arterial degeneration. Enlargement of the heart is a common complication of chronic renal disease, especially in the non-exudative or cirrhotic form. It may also occur in chronic diffuse nephritis with exudation. These forms of chronic renal disease give rise to a number of very definite symptoms which are characteristic of them. There is the hard incompressible pulse of arterial sclerosis, which causes great derangement in the blood supply to the various organs of the body. This diseased condition of the arteries is a common cause of apoplexy and the interference with the circulation gives rise to definite cerebral symptoms. First, impairment of memory due to anæmia and malnutrition of the brain. Second, a persistent tendency to wake too early in the morning. Third, vertigo, especially in the morning after getting out of bed. Fourth, headache with persistent painful cramps in the calves of the legs in the morning before or after rising. Fifth, a vague sense of fear, as of some impending danger. In addition to these the intellect is greatly impaired, patients become dull and apathetic. The urine is of very low specific gravity and albumin and casts are usually found. It is generally very light in color and abundant in quantity. Important information is often derived from observations made on the arterial system in addition to that of the heart. The frequency of the pulse should be noted, but the nature of the pulse is of more importance than the time or rate. A strong incompressible radial pulse indicates enlargement of the heart with high tension. A weak, compressible, and perhaps irregular pulse indicates fatty degeneration, dilatation, or anæmia. In high arterial tension the artery is hard and cord-like, and can be rolled underneath the finger and easily traced up the forearm; as this pulse is often small, owing to the contraction of the arteries, it might be mistaken for a weak pulse if it were not always incompressible. Many conditions give rise to high arterial tension, among which may be mentioned renal cirrhosis, degeneration of the arteries, or arterial sclerosis, gout, lead poisoning, chronic poisoning by ergot, etc. In arterial degeneration the vessels become elongated and pulsate visibly, and calcareous plates are often found in the radial artery. Atheroma, when present, exaggerates the pulse by giving it a feeling of strength which is deceptive. Consequently persons are found having atheromatous arteries in which the pulse has a fictitious strength. Atheroma is a very significant condition indicating senile degeneration of the arteries, a process which quickly leads to atrophy.

Arrhythmia, or intermission, occurs when one or more beats of the heart are skipped. Irregularity consists of alternate beats, unequal in volume or force, or there may be a systematic coupling together of the

¹ Read at the meeting of the Medical Society of the County of New York, March 23, 1896.

beats in pairs, or the heart's action may become alternately rapid and slow. Irregularity of the pulse is found in fatty degeneration of the myocardium, chronic meningitis, and in the excessive use of tobacco. It should be clearly understood that an irregular pulse is of far more serious significance than an intermittent one. Some persons have intermittency of the pulse for many years and it does not seem to imperil life. If intermission occurs after prolonged or violent exercise it then becomes more serious.

Tremor Cordis is a peculiar form of irregularity of the heart's action. It is not caused by mental emotion or physical exertion. It sometimes occurs in young persons, but is more common in the old. The heart is suddenly seized with a rapid tremulous sensation lasting for a few seconds only. The pulse instantly collapses to a mere threadlike feeling and transmits a distinct trembling, oscillatory sensation to the examining finger. The attack usually begins by several very rapid, tremulous, incomplete, systolic contractions and may continue for several seconds; more often the duration is less. The sensation of the patient during the attack is that of imminent death; syncope has never been observed during a paroxysm. Tremor cordis is a prominent symptom of cardiac dilatation, and may occur as the result of flatulence caused by indigestion. It is claimed that sudden inhibition of the vagus will also cause it. Pain or palpitation has never been observed as symptoms of this condition.

Tachycardia, or heart hurry, is a grave symptom if occurring in advanced age. In infant life it is physiological, the pulse rate of the new-born child being about 130 per minute. In pathological tachycardia the pulse rate may reach 120 per minute or more. The pulse is usually feeble and sometimes almost imperceptible; the respirations are generally increased. Paroxysmal tachycardia is a condition characterized by extreme rapidity of the heart's beat: the pulse may reach 200 or more per minute. The respirations are increased up to forty per minute or even higher. It has been claimed that the increase in the heart's action is caused by shortening of the diastole so that during the systole very little blood is expelled from the heart, and that the usual amount per minute is not increased. During the attack the patient is not disturbed and is quite unconscious of the extreme rapidity of the heart's action. This is in strong contrast to palpitation, which is often confounded with tachycardia. Heart hurry is produced by a number of causes, among which are abnormal irritability of the nervous system, heart strain, cardiac dilatation, mitral stenosis, and all forms of senile cardiac degeneration. The excessive use of alcohol is a common cause of tachycardia. This does not refer to the temporary or moderate use of alcoholic spirits, which increases the frequency of the pulse for the time being, but to that produced by the chronic abuse of alcohol, which causes a fatty degeneration of the myocardium, thus weakening the cardiac function and also producing a neuritis of the pneumogastric which paralyzes its inhibitory action on the heart. This condition is always accompanied by weak heart sounds, and a feeble pulse. Tobacco in small and repeated doses produces intermission, slowness, and sometimes irregularity of the pulse, but when the dose is large enough to paralyze the pneumogastric and the heart is freed from its inhibitory action, an attack of paroxysmal tachycardia is imminent. The abuse of tea and coffee may also lead to an attack. Digitalis, when given in medicinal doses, slows the action of the heart, but when given in too often repeated or large doses it causes paralysis of the vagus. The pulse is at first slow, then skips a beat or intermits, and finally, when the inhibitory effect of the pneumogastric is lost, the pulse becomes regular

and extremely rapid, and tachycardia is established. This also occurs as the result of chronic poisoning by belladonna or atropine. Toxic doses of these drugs paralyze the pneumogastric and this is followed by an extremely rapid and feeble pulse with weak heart sounds. Tachycardia is also caused by many lesions of the brain, tumors, or aneurisms pressing on the vagus nerve. Reflex tachycardia is generally of short duration and accompanied by a number of definite neurotic symptoms; flushing of the face, dilatation of the pupils, hot flashes, and other changes, indicating reflex action through the sympathetic. The pulse is full and the cardiac impulse strong, quite the opposite to that found in tachycardia due to vagus inhibition. The irritable heart of soldiers during the civil war, described by Da Costa, belong to this class. In all his cases the pulse was increased to 100 or even as high as 140 per minute. Pepper saw a case in which the pulse varied from 220 to 240 per minute, the paroxysm lasting for fifteen hours.

Brachycardia is the term used to indicate a slow action of the heart. A slow pulse is sometimes found in early life and attended with perfect health. Slowness of the pulse occurs in the puerperal state; in recovery from the acute fevers, like pneumonia, acute articular rheumatism, and diphtheria; in diseases of the digestive tract, like cancer of the stomach and chronic dyspepsia. It can be produced by the action of various toxic agents and may occur in anæmia, chlorosis, and diabetes, also in paresis, mania, and melancholia. It is most frequently found in dilatation of the heart. One of the most constant causes of slowness of the pulse is produced by an injury to the cervical portion of the spinal cord, and especially if the lesion is situated near the origin of the spinal accessory nerve. A slight concussion of this portion of the cord will produce temporary slowness of the pulse, while a lesion involving injury or compression will produce permanent brachycardia. The injury to the spinal cord may be traumatic, as by blows and falls, or by disease of the cervical membranes, viz., pachymeningitis by compressing the cord will permanently slow the pulse. Balfour claims that the Indian fakirs slow the heart and diminish the force of its beat by compressing the muscular branches of the spinal accessory. The pulse in brachycardia may be reduced to forty or even to twenty per minute. Jacobi cites a case in which the pulse rate was reduced to seven per minute. Hemisystole has been claimed as a cause of slowness of the pulse. In hemisystole only every second or third beat of the heart is strong enough to reach the artery, giving the false impression that the heart beat is slow. Brachycardia occurring during or past middle life is always a pathological condition, and is sometimes associated with a neurosis of the heart itself.

Delirium Cordis.—For many years the pulsations of the heart may not exceed twenty or thirty per minute and yet the action of the heart is perfectly regular, but when brachycardia is caused by inflammation of the myocardium the heart's action may become irregular, with intermissions and complete cessation of the pulse, lasting for a second or more, and thus leading to an attack of delirium cordis. Consciousness is lost with the loss of the heart's action. The face turns deathly pale, convulsions may be general; more often they are confined to the muscles of the face and neck, with foaming at the mouth. With return of the heart's action consciousness is regained; the face reddens and then becomes cyanosed. These attacks are precisely like the convulsions sometimes seen in epilepsy, with great slowness of the pulse.

Orthopnœa, or inability to breathe in the horizontal posture, is a symptom belonging to the later stages of heart disease. It is often caused by interference

with the diaphragm and is produced by flatulence and overdistention of the stomach and bowels. I believe that the disturbed circulation in the medulla owing to the irregular action of the heart is the principal cause of this condition. Patients usually wake up suddenly with violent palpitation.

Angina Pectoris, or breast pang, is a severe neuralgic pain, often accompanied by muscular spasm of the heart. Any muscle when cramped gives rise to a severe pain, owing to the pressure on the nerves caused by the muscular contraction. In angina pectoris the patient feels as if he were going to die. The pain radiates to the left arm and sometimes upward to the neck. This pain is of an unusually severe form, but it is not the severity of the pain alone which makes it so intolerable, but the sensation of impending death which follows it. The aspect of the patient is characteristic of the agony which he endures. The face is pale and bloodless, and covered with perspiration; the breathing is shallow; the pulse is small, wiry, and generally irregular; sometimes it may be regular. The pain radiates to the left shoulder and down the left arm to the hand and fingers. It may radiate down both arms simultaneously. I have seen a case in which the pain radiated to the right side only. During the attack the patient scarcely breathes, owing to the fear of impending death. Some attacks are more severe than others. The pain varies; sometimes it is dull and agonizing; at other times it flashes quickly up to the left arm and down to the fingers, accompanied by the greatest agony. Palpitation is a prominent symptom during the attack. Coronary sclerosis and fatty degeneration of the myocardium are prominent causes of angina pectoris. Deficient blood supply to the heart caused by embolism or thrombosis is another important factor. Anything that will diminish the normal amount of blood to the heart will induce angina. Atheroma, therefore, is a common cause. It is also a constant concomitant of advanced cardiac dilatation, strange to say, but pain is sometimes absent in true angina, the so-called *angina sine dolore*. These cases occur with dilated hearts, and are often mistaken for asthma. The prognosis is not always unfavorable in angina; some cases recover under treatment.

Cardiac Pain.—Pain in the heart more often complicates aortic than mitral disease. It is paroxysmal in character and often described as a cutting or tearing sensation. It is greatly intensified by muscular fatigue and aggravated by palpitation. True cardiac pain is generally localized and confined to the region of the heart. Sometimes, however, it may and does radiate up to the left shoulder and axilla. It is almost always accompanied by numbness and tingling.

Dropsy.—This is a prominent symptom of advanced heart disease. The lower extremity is usually first affected. In some cases the swelling may reach the knee and remain there or even recede. In other cases the œdema increases, involving the scrotum, peritoneum, pericardium, the pleura, and even the ventricles of the brain. The skin is dense, shiny, and red, and in some instances may take on inflammatory action. This may be associated with orthopnea, dyspnea, and lividity. It is not often easy to distinguish between dropsy of renal and of cardiac origin, for albumin and casts are often found in the urine of both. In renal dropsy the œdema first appears underneath the eyelids. This is more prominent in the morning, and may subside during the day. The skin is pale and waxy in appearance, in marked contrast to the venous stasis, cyanosis, and lividity of cardiac disease. The external genitals are invariably irritated in renal disease, but not so in cardiac dropsy. Bronchorrhœa and hæmoptysis are frequent symptoms of chronic valvular disease of the heart. Epistaxis is most frequently found in mitral disease.

Insomnia is a most persistent and very distressing symptom, and if dyspnea is present the loss of sleep is added to the suffering of the patient. The sleep is not continuous and often very restless and frequently disturbed by frightful dreams.

Cerebral Symptoms are caused by disturbance of the equilibrium of the circulation and an insufficient amount of arterial blood, giving rise to unpleasant dreams, hallucinations, sudden starts, etc. Physical disturbances are manifested by a complete change in the character of the individual: finally, there are hepatic and renal changes, giving rise to ascites and dropsy and greatly modifying the original disease, producing gastric symptoms with vomiting.

There are two remedies always required in every case of heart disease, *i.e.*, oxygen and iron. The amount of iron in the blood determines the amount of oxygen carried to the various tissues of the body. All the active tissues and organs require a definite amount of oxygen for the discharge of their various functions; but the muscular system is solely dependent on oxygenation for its development and activity. The muscles are the moving-instruments of bodily mechanism and therefore carry on the circulation. The nervous system may regulate the circulation, but without the former the latter could not act at all. The circulation, arterial, venous, and lymphatic, is dependent on the amount of muscular power developed by the heart, arteries, capillaries, and veins; and when it fails and congestion takes place it is due to the failure of the muscular apparatus of the heart. Oxygen is the motive power of the muscles, and muscular power depends on the activity of our breathing muscular power, therefore is in direct proportion to the efficiency of the respiration. Respiration and its influence on muscular action is in direct proportion to the amount of oxygen taken into the lungs. It is now known that valvular lesions are not by any means the chief cause of heart failure, but that heart disease is more often the result of muscular weakness of the myocardium and the arteries. The circulation becomes embarrassed and the heart is, owing to deficient oxygenation, unable to overcome the obstruction. The heart enlarges, but owing to the weakness of the myocardium it soon begins to dilate. It should be remembered that in all cases of heart disease the great danger is from muscular weakness, and oxygen is the only remedy. Therefore iron is always indicated and should be given from ten to twelve times a year, for a period of three weeks at a time: at the same time the patient should be placed in open air daily.

Digitalis is the leading cardiac stimulant. It causes a tonic contraction of the walls of the ventricles. This action is not uniform; some of the fibres are affected while others are not. This contraction is due to the prolongation of the systole and shortening of the diastole. The cumulative effects of digitalis are sometimes produced where it has been given for a time in too large doses. These consist of persistent nausea and vomiting, with intermittency of the pulse. The dose should never be large enough to produce these symptoms. Digitalis is a great remedy for dilatation, and the heart remains small and contracted while under its influence. Unfortunately, however, it has another action that is a serious drawback to its administration. It contracts the muscular coats of the smaller arteries at the same time that it acts on the heart. This results in an obstruction which neutralizes all the good effect of digitalis on the heart. Now to overcome this obstruction in the arterioles vascular dilators are employed, and nitroglycerin is very effective for this purpose. It should not be given in larger doses than one one-hundredth of a grain at the beginning. The action of nitroglycerin in relaxing the arteries is very similar to that of amyl nitrite,

but the effect of the former is more permanent. It is therefore especially indicated in high arterial tension, which means diminution of the calibre of all the arteries throughout the body, with a great tendency to dropsy, owing to the venous current not receiving proper impulse. Nitroglycerin is of great value in the treatment of chronic interstitial nephritis with a hard incompressible pulse and general arterial sclerosis, in conjunction with corrosive sublimate, the muriated tincture of iron, and the sweet spirit of nitre, as in the following:

R Hydrargyri corrosivi chloridi gr. i.
Tincturæ ferri chloridi..... ʒ ij.
Spiritus ætheris nitrosi ʒ ij.
Aque ʒ iss.
Elixiris simplicis..... ad ʒ iv.
M. S. One teaspoonful in water after each meal.

Tablets of nitroglycerin containing one one-hundredth grain each should be taken in conjunction with the above. If this dose is well borne it may be increased up to one-fiftieth or even one-twentieth of a grain. Nitroglycerin is very useful in angina pectoris. It should be given four or five times through the day, the last dose at bedtime. Amyl nitrite is a vascular dilator and an anodyne as well. Inhalation in a large majority of cases will instantly relieve the pain and spasm of angina pectoris. There is no danger in using it freely if the arteries are healthy. I have known sixty drops to be inhaled from a handkerchief before the pain and spasm were relieved. Sodium nitrite in doses of one to two grains is a very useful vascular dilator and stimulant. It may not be well known, but potassium iodide is equally effective and regarded by some as superior even to nitroglycerin as a vascular stimulant. It is slow in its action at first, but when its effect is once secured it can be easily maintained in doses of five grains three times a day. The iodide is best given largely diluted with milk and taken on a full stomach. Strophanthus in some respects is superior to digitalis. It seems to act more definitely and quickly. It produces a strong, steady, uniform systole, and does not seem to contract the arteries or raise the blood pressure as soon as digitalis. Except in special cases the dose should not exceed ten minims of the tincture. Strychnine is a powerful cardiac stimulant. The dose should be small at the beginning, not greater than one-sixtieth grain. This can be increased up to one-twentieth grain, or even as high as one-twelfth grain, or until toxic symptoms appear. Strychnine is one of the best stimulants for a weak, feeble heart, and may be advantageously combined with belladonna or atropine. Sparteine sulphate in doses of two grains and barium chloride in doses of one-sixth to one-half grain are useful; also caffeine citrate in doses of one to four grains. A combination of all of the cardiac stimulants taken together act very much better than any one of them alone. The nitrate of silver if taken for some time in one-fourth grain doses will often relieve the pain of angina pectoris. Small doses of arsenic are sometimes useful in conditions of senile degeneration of the heart and arteries. Colchicum is of benefit in every case of irregularity of the pulse due to a dilated, gouty heart. Intestinal antiseptics are of great value in the treatment of chronic heart disease. Salol and bismuth are very useful for this purpose in six-grain doses three times per day. Active purgation is always indicated, as it lowers the blood pressure and prevents flatulence. A very good preparation for this purpose is the compound jalap powder.

Insomnia is a very distressing symptom of advanced heart disease and hypnotics are required to produce sleep. Morphine is the best remedy for this purpose, and may be given in doses of one-fourth grain with twenty grains of sodium bromide. There is no doubt

whatever as to the superiority of morphine over all other remedies for the relief of cardiac insomnia. It stimulates and regulates the heart and quiets the patient in a way that no other remedy does. Codeine can be substituted for morphine at times, and it always acts very well in doses of from one-fourth to one grain. Trional is a very useful hypnotic in doses of from ten to fifteen grains. Chloral is undoubtedly the most perfect hypnotic, but owing to its powerful sedative action on the heart it should be always combined with morphine. It can be safely given in doses of ten grains with one-fourth grain of morphine sulphate. Sulfonal can be given in thirty-grain doses in hot soup. Somnal often acts very well in twenty-minim doses given in a little sweetened water or syrup of licorice. Paraldehyde is a useful but very disagreeable preparation. It can be given in doses of forty drops every three hours until sleep is produced. It is best given in syrup of ginger.

WE ARE DRIFTING—WHITHER?

By FRANK VAN FLEET, M.D.,

NEW YORK,

ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL; INSTRUCTOR IN DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL, ETC.

I HAVE before me as I write a printed circular letter which was forwarded to me by a lady patient, a school teacher. It is addressed to "Dear Madam," and is intended for distribution to school teachers. It speaks of the evils attendant on uncorrected eye strain, not alone in producing defective vision, but also in its effect on the general health, producing nervous derangements, etc., and ends as follows: "The large number of New York's best physicians who send us their patients when they suspect eye strain vouches for our reliability. We would be happy to be of service to your pupils or yourself. The inclosed card entitles you to a special teacher's discount."

This is a sample of the many pitfalls which meet our infant feet, and, unfortunately, continue with us, surrounding us on all sides through life. In this particular instance the worst feature of it is that we of the medical profession are responsible for it.

It has long been known that many serious consequences result from neglect of the eyes of young children, and educators generally are familiar with the fact that often a dull and backward child will become the brightest in his class when glasses are properly fitted to his eyes. I took occasion to speak on this matter before the New York County Medical Association in a paper entitled, "The Necessity of Perfect Vision in the Education of the Young," in October, 1893,¹ on which occasion I dwelt carefully on these troubles, which are reflexes due to accommodative strain. I but followed in the steps of illustrious predecessors, and it may safely be said that nearly everybody, lay and professional, is familiar with the facts.

A very large percentage of the world's population has defective eyes; just how large it is impossible to state, as we find the percentage increasing as the years roll by.

A very interesting study is a comparison of percentages obtained from the examination of eyes to-day and those of twenty years ago. The only sources of information for such a study at our command, furnishing large numbers of cases, are the annual reports of the different eye clinics. The percentages here do not, however, present the exact proportion of refractive cases, because we find that, large as this class is, it is smaller proportionately than the number one meets with in private practice. For example, we find the

¹ See Gaillard's Medical Journal, December, 1893.

statement made in one text-book that in private practice the proportion is twice as great as it is in the clinics.¹ I imagine, too, that this differs very much in the practices of different men; it certainly varies in institutions. I give below a table of comparisons, the data for which were obtained from the annual reports of the Manhattan Eye and Ear Hospital, the New York Eye and Ear Infirmary, the Ophthalmic and Aural Institute, all of this city, and the report of the Wills Eye Hospital of Philadelphia, which were the only reports I had at my disposal. I have no doubt, if the number of institutions were larger, the proportions would be the same.

	Cohn's Tables (European). Sixty-seven institutions, 1875-300,000 cases.		Three New York City Institutions, 1894-34,820 cases.		New York Ophthalmic and Aural Institute, October 1, 1893 to October 1, 1894-7,500 cases.		New York Eye and Ear Infirmary, October 1, 1893 to October 1, 1894-16,125 cases.		Manhattan Eye and Ear Hospital, October 1, 1893, to October 1, 1894-17,201 cases.		My Summer Clinic, Manhattan Eye and Ear Hospital, June 1, 1895, to September 16, 1895-838 cases.		Wills Eye Hospital, Philadelphia, Pa., 1894-12,614 cases.

15. Various	1.5	5.6	0.8	10.2	1.7	1.0	..							

a, Iris and ciliary body. b, Choroid and vitreous. c, Globe and orbit. d, Muscles alone.

The chief interest in the foregoing table centres in the first two columns of figures, which are a comparison between the relative frequency of affections of the eye twenty years ago and to-day. It will be noticed that the differences are slight except in one particular, and that is in refraction and accommodation, No. 10 in the list. It will be noticed also that where the percentages are less in the second column, the differences, small as they are singly, together go to make up a large proportion of the increase in No. 10. For example: in No. 1, a decrease of 0.8 per cent.; No. 2, 5.4 per cent.; No. 14, 1.8 per cent., making a total of eight per cent.; while in No. 10 there is an increase of thirteen per cent. Indeed, we find decreases in the second column all along the line; out of fifteen items there are decreases in eleven. It is easier to explain the decreases than some of the increases, still they can be explained. The increases occur in items 10, 11, 13, and 15.

In No. 15, under the heading "Various," are included unclassified and unrecorded diagnoses, improper cases, etc. Of 5.6 per cent. of various diagnoses, 4.2 per cent. were unrecorded. In one institution the total of lost or unrecorded diagnoses was 9.7 per cent. In No. 13, "Affections of the Orbit," there is an increase of 0.3 per cent. In No. 11, "Muscles and Nerves," an increase of 1.5 per cent. is accounted for by the increased attention paid to errors of this class; while in No. 10, "Refraction and Accommodation," an increase of thirteen per cent. marks the march of

progress and civilization. Altogether we find the decreases amount to 19.1 per cent., while the increases amount to 18.7 per cent., a difference of 0.4 per cent., probably due to some error in obtaining the percentages. It is trifling and does not affect the deduction to be drawn from the whole.

I believe many instructive lessons can be drawn from these figures; it is possible that the increase in refraction cases may account for some of the decrease in lenticular troubles—as in cataract, for example.

Then, too, we have frequently seen cases of astigmatism diagnosed as retinitis and neuritis; indeed, many conditions formerly classified as diseases are, with our improved methods of examination, now recognized as refractive.

The most striking feature of this report and the one to which I desire to call especial attention, is this one of refraction and accommodation, which is increasing as the years go by and which, as I said above, is a criterion of our intellectual growth. Eyes do not change from one generation to the other. It was said years ago that fully ninety per cent. of the human race were hypermetropic, and in looking over the list of affections of the eye in the Manhattan Eye and Ear Hospital Report for 1894, we find among the cases of refraction ten per cent. of myopia. No; the cause for the increase of refraction cases is not deterioration of the eye, but increase in the necessity for correct vision. Farmers and people whose work is out of doors, calling for very little exercise of accommodation, do not as a rule require glasses; but the inhabitants of cities, where the occupations require prolonged and accurate work at short range, these are the people who require artificial aid through the medium of glasses. The tendency of population is toward the cities, and here the demand for positions in which one can earn a living so exceeds the supply that defective vision places one entirely out of the race.

This necessity for perfect vision, or for means whereby it can be obtained, has brought about a revolution in the methods of examining eyes and of preparing lenses. It has also brought forward a class of people who, ill prepared to do that which they advertise to be able to do, work harm to the community the evils of which can hardly be estimated. Here is a position in which the medical profession should take a decided stand. Not only do they owe it to themselves and to the future of the profession, but to the public which, as the showman said, delights in being humbugged.

Recent years have seen the medical profession take enormous strides toward perfecting its members in raising the standard of proficiency. It is impossible in this and many other States for a candidate to enter upon the study of medicine until he has shown his general knowledge, which is rightly considered necessary to a proper understanding of the healing art. The candidate must undergo an examination by the State before he can enter a medical college. Here he must devote three or more years to study and pass a final examination before he is entitled to the degree of doctor of medicine. The degree his college confers on him does not give him the right to practise his profession, but he must needs pass another examination by the State, which, if he pass it successfully, qualifies him to become a practitioner of medicine.

This preparatory course, which was not forced on the profession but which is the work of their own hands, gives to the public a protection for which it cannot be too thankful. But while the aspirant for medical honors is turned out a thoroughly qualified physician, he enters a field where he finds himself forced to compete with men in certain branches who have not been trained, who, often with a few weeks or at most months of familiarity and with the most superficial knowledge, flaunt themselves before the public

¹ "Diseases of the Eye," by P. B. St. John Roosa.

with impunity as practitioners of an art which the physician has acquired with the greatest difficulty.

The physician endeavors to obtain a lucrative practice, but finds himself restricted to the privilege of placing a sign at his office door and to those favors he may receive from his friends. The unlicensed and unqualified, on the other hand, resorts to the newspapers for advertisement if he so desires, or floods the country with handbills and circulars, one of which, as I said in the beginning of my paper, I have before me as I write.

It seems a simple thing for one man to test the eyesight of another, and, finding the glass which gives him the best vision, to prescribe it and say, Go and be happy. If one has reached a presbyopic age this may be all that is necessary; but headache, neuralgia, nervousness, chorea, and a host of other manifestations, may or may not be due to defective eyes, and because we find in the possessor of optical defects these coincident troubles it does not follow by any means that one is the cause and the other the effect.

The ophthalmologist knows too well how many unfortunates there are who have lost time travelling from one optician to another for the relief of headache, neuralgia, nervousness, etc., until finally they come to the doctor in despair, only to find that during the time they have spent wandering about their disease has made such strides that death is inevitable. This sad picture has been presented to me not a few times, and conversation with my fellow-practitioners shows it to be all too common.

The headache, the neuralgia, the occasional double vision, the at times distorted vision, may mean incipient kidney trouble, malaria, rheumatism or gout, commencing spinal disease, and many other conditions, the recognition of which may be easy or difficult to physicians, but impossible to the untrained mind and the uneducated glance.

Our medical laws designed to prevent the practising of medicine by the unqualified are very inadequate and inconsistent. They not only allow manufacturers of trusses and artificial eyes to fit their manufactures to persons in need of them, but also allow them to judge who is in need. It is possible, I believe, to apply a truss under these circumstances to a strangulated or incarcerated hernia, and thereby produce death, or insert an artificial eye in an orbit where its presence might produce sympathetic trouble in the eye of the opposite side, the result of which might be blindness or even death. The laws do not allow opticians to fit glasses for neuralgia and other conditions which are, no matter what the cause, medical.

These laws should be so modified that the application of a truss, an artificial eye, or a pair of glasses, would never be made except on the advice and prescription of a competent physician; and by competent I mean legally qualified.

The body of men known as chiropodists have succeeded in having a bill passed whereby they have a legal standing which allows them to restrict their numbers and also to perform certain surgical operations on the feet. I have not seen this law, but I know that any measure giving such privileges to any body of men who have not complied with the law governing practice is an injustice to those who have devoted years of study for the same privilege, and is altogether wrong.

But these conditions, wrong as they are, exist. The latest scheme is one being promulgated among and by the opticians, designed to give them the same advantages. They propose the organization of a body whose purpose shall be twofold: First, to secure legislation compelling newcomers to pass an examination by one or more of their own members—though where they themselves received their qualifications it would be

difficult to say—by which means they will limit competition; and second, to prevent legislation emanating from the medical profession tending to restrict their field.

Year after year the march goes on, and educated men, finding an entrance into the profession growing more and more difficult, and practising physicians, finding the conflict with these inferior competitors becoming greater and greater, will be forced to resort to measures of self-protection. What will these measures be? Why do practitioners of medicine so often have their sons follow some other calling? Why is it we hear the rumblings of discontent in the rank and file?

The medical profession is one an intimate association with which fills one with nobler thoughts and makes one more in touch with the finer feelings of humanity than any calling of which we have knowledge. It is right, it is just that we should require a high standard in applicants for admission into our ranks; it is equally true that we should be jealous of our rights, not only for our protection, but also for the protection of the public, of whose health we are the custodians. But whither are we drifting?

116 EAST EIGHTY-SECOND STREET,
January 15, 1896.

INEBRIETY AND ITS TREATMENT BY HYPNOTISM.

By ANI DE JONG, M.D.,

THE HAGUE, HOLLAND.

I BELIEVE nobody will disprove the claim if I hold, without depreciating all the good it has produced, that the invention of alcohol and of alcoholic drinks, has brought on mankind one of the greatest calamities.

The great destructions, moral as well as material, among all civilized nations, caused by alcoholic drinks are so generally known that they do not need further to be cleared up.

It is very easy to understand that men have tried everywhere by all sorts of means to prevent this horrible abuse, and happily we can confess that during the course of time the founding of many philanthropic societies of temperance, new laws on the traffic in alcoholic drinks, more severe penalties for public drunkenness, the erection of popular coffee houses, etc., have brought about in many countries great improvement as to the abuse of spirits and other alcoholic drinks.

I have not the intention to give a description in general of what has been done and what still is done every day to prevent and to cure inebriety. This I leave willingly to other persons more competent than myself. I only wish to communicate in a few lines my experiences in the treatment of inebriety in special cases.

Some people think that the treatment of inebriety does not belong to the profession of the physician. They pretend that the physician should treat only pathological disorders, diseases produced by alcoholic abuses, but that the treatment of inebriety itself, it being merely a bad habit, must be left to the police and to the moralists occupying themselves with the treatment of drunkenness.

I very willingly admit that inebriety in a great number of cases is caused by bad habits, like a great number of other diseases, but we cannot therefore say that inebriety is only a bad habit. My opinion is that inebriety is a very serious mental disease and that its treatment belongs in the first place to the medical profession. If we examine exactly the origin of a great number of cases of drunkenness, we shall

find that many among them belong in families in which mental and nervous diseases are numerous; that is to say, in other words, that many drunkards are predestined hereditarily to mental and nervous diseases, a predestination we can explain only as being a degeneration of the nervous system, while reciprocally drunkards produce a great number of descendants suffering from mental and nervous diseases.

These facts demonstrate that there exists a great affinity between inebriety and mental and nervous diseases.

If we fix our attention on the drunkard himself, generally we find an alteration of his whole personality, a change of his character, a diminution of his intellectual faculties, a diminution proceeding to a total destruction of the moral sentiment—in one word, a psychical revolution, which is to be explained only by pathological alterations of the organ of the intellectual life, of the brain.

That alcoholic intoxication provokes pathological alterations is proved by physiological experiments and anatomical researches. Physiological experiments have proved that when alcohol is introduced into the body a great deal leaves the body unaltered, that another part remains in the body, and that the greatest part of this is deposited principally in the brain and in other parts of the nervous system. Our knowledge of the influence of alcohol on nervous tissues outside the body is perfectly in harmony with the anatomical alterations of the nervous tissues of drunkards found after death.

This is not the place to give an exact description of the details of these alterations. It is sufficient to know that they consist principally in a destruction of the nervous elements which are indispensable to the normal functions of the brain and the other parts of the nervous system.

Some have made the objection that all this does not prove that inebriety itself is a disease; that all these anatomical alterations in the various parts of the nervous system and all the psychical aberrations which they cause are provoked by the habitual abuse of alcoholic drinks. But can we imagine that if inebriety were only a bad habit, the person addicted to it, seeing all the misery, the dishonor, the unhappiness of his family, the material and moral ruin which threatens him, would not and could not resist it? But he cannot resist; he possesses no longer the faculty of willing; his free will is lost; he is a psychical invalid.

The question is: Is inebriety a curable disease? Incontestably there are drunkards who resist all modes of treatment, but happily there are also others. The experience of many observers and my own as well have taught me that in a great number of cases of chronic alcoholic abuse we obtain very good results by a careful and exact treatment, if it be continued long enough. How should inebriety be treated?

The treatment of inebriety must be directed, in the first place, to the alcoholic abuse; in the second place, to the psychical and physical invalidism. The treatment of inebriety generally employed is the moral treatment. We have seen that one of the disorders caused by alcoholic abuse is a diminution of the moral sense which proceeds to a total destruction; that is to say, the faculty to receive moral impressions is reduced to a minimum and therefore it is clear that a moral treatment cannot have much success.

Before beginning a moral treatment it is necessary that the patient abstain totally from taking alcoholic drinks. A total abstinence continued long enough will be sufficient in most cases to restore to the patient the moral impressionability. But knowing by experience that it is not easy in most cases of inebriety to bring the patient to a voluntary abstinence,

we are obliged to force him by some means to abstain from alcoholic drinks. This is possible, in the first place, by transferring the patient to an asylum where he is rigorously watched; in the second place, by employing means which produce a loathing for alcoholic drinks. The treatment in an asylum involves in many cases great difficulties.

It is to be hoped that before long there will be everywhere laws compelling the drunkard to be treated in an asylum and to remain there until he is quite cured. At present, however, treatment in an asylum is not possible without the consent of the patient himself and nobody can force him to remain there until he is cured.

But there are still other difficulties; for a number of people are not able to pay the expenses of a long sojourn in an asylum. And not only this; sometimes persons who abuse alcoholic drinks are still able to work and to support their families. If they go to an asylum they inevitably expose their families to poverty and misery.

Another great difficulty may be noted by the following question: How are persons leaving the asylum quite cured and going back to society, generally received? Public opinion is not always just. The public does not always forget and forgive. Generally it will not or cannot believe that a drunkard is curable. Once a man is a drunkard, in the eyes of the world he always remains a drunkard.

If I enumerate all these difficulties it is not to oppose treatment in the asylum. A well-managed asylum is a very useful institution. But there is another treatment which does not present these difficulties, one which offers the advantage that the patient can remain at work during treatment and gain the bread for his family, if he is still able to do it; furthermore, the expenses are not great. My conviction is that this treatment ought to be employed before sending the patient to an asylum. I refer to the treatment by hypnotism and suggestion.

Employed by a scientific physician who is perfectly conversant with it, hypnotism can do no harm to the patient and offers the great advantage that in most cases we can provoke in a very short time an aversion to alcoholic drinks. In many cases I was able in the first séance to excite such an aversion that the patient could not smell alcoholic drinks without vomiting.

Another advantage of this treatment is that in the hypnotic state the patient is more susceptible to moral impressions than when awake. Some people pretend that the physician has no right to provoke such an aversion to alcoholic drinks. They call this suggestion immoral, in that it interferes with the free will of the patient. I must remark that this objection is not quite just. I willingly admit that when suggesting to a drunkard, as I always do, that it is not possible for him to take alcoholic drinks, that at the moment he takes them he will vomit, etc., I cross him in his will of drinking. But can we attribute a free will to the drunkard, the slave of his passion? Is his will not bound by the irresistible desire to drink? If I bind his will on the one hand, it is in his own interest; it is to save him; it is to give him back, on the other hand, his free will against his passion.

As I remarked before, the patient is more susceptible to impressions in the hypnotic state than when he is awake. The ideas suggested in hypnotism are more easily accepted by the brain and remain there better fixed, all attention is concentrated on the suggested ideas, and the contrary ideas, not entering the brain, cannot weaken the suggested ideas.

This treatment of inebriety has given me very interesting results. Other physicians, as Dr. Liébeault, Professor Bernheim, Professor Forel, Professor von Krafft-Ebing, Dr. Berillon, Dr. Wetterstrand, Dr. von

Schrenck Notzing, and others, have published very good results of this treatment.

I myself have treated thirty-four patients and they have given me the following results: Eight went away not cured. The other twenty-six patients were all under my care until I believed they were cured and discontinued the treatment. Of these I know that fifteen do not drink any more, and in the case of some of these the period of total abstinence has lasted many years. Of the other eleven patients I believe that seven were cured, but I never saw them again. Four I know have relapsed into their drinking habits, because they were again exposed to temptation.

Of the eight patients who went away, one abstained for four months, and it was the fault of his wife that he began to drink again. I believed him nearly cured and told him to come once a month, and as he did not come on the fixed day I wrote to his wife and asked her to visit me. She came, and when I asked her if she was satisfied with her husband and with the results of the treatment she answered: "No, doctor, I am not content at all. It is true that my husband has not taken any spirits since your treatment, but since he takes no spirits any more he is quite another man. Before he was a jovial, pleasant fellow, but now he is a dreamer; for me he is nothing more; I have lost in him my husband. I prefer a great deal that he take his dram as before." Another who went away, an artilleryman, had been some weeks under my treatment and really with success. He abstained totally for some time, but one day when he was due at my clinic he did not come. He never came again, and one day I met him in the street and asked him why he did not come any more to be treated. "I am sure," I said, "you have taken spirits again." He answered: "Yes, doctor, it is so. My comrades teased me always, so that I could no longer abstain, and consequently I was obliged to begin again to drink. But, doctor," said he triumphantly, "I cannot drink gin any more; I drink only brandy."

I relate these few interesting cases only to show that a patient once having abstained for a long time and really being in a fair way of being cured, must not be in the society of persons who oppose the treatment. His family and his friends must help the physician. They must do all they can to render the abstinence light and easy for the patient. They must treat him with compassion and try to forgive him and forget all the wrong that he has done, and they must do as much as possible to raise him physically and morally. Under these favorable circumstances, I am convinced that a great number of drunkards can be cured and become again useful and honorable members of society.

23 LANGE VOORHOUTS.

Serum Injections in Secondary Syphilis.—Vieo-rovsky reports (*Semaine Médicale*, No. xv., 1895) having treated five cases of secondary stage with subcutaneous injections of serum obtained from the blood of robust persons in the tertiary stage. The serum was filtered and 0.5 per cent. of carbolic acid added. From four to twenty cubic centimetres were injected in the scapular region. There were from twenty-one to twenty-three injections in each case. The results were general improvement, healing of the initial lesion, and more rapid disappearance of the eruption. Mucous patches showed the least improvement, and the relapses were more rebellious to the treatment than the early symptoms.

There are two things I have never seen succeed in practice: to speak ill of a confrère and to buy your patients by charging a small fee.—ALLISON.

Progress of Medical Science.

The Universality and Antiquity of Adenoid Vegetations.—In an interesting address delivered before the Copenhagen Medical Society, published in the *Hospitalstidende* of February 6 and 13, 1895, and translated in the *Archiv für Ohrenheilkunde*, December 30, 1895, the late Dr. Wilhelm Meyer showed from statistics, from portraits of historical personages, and from a study of antique busts preserved in the Vatican Museum, that hypertrophy of the pharyngeal tonsil is an affection of universal prevalence at the present day and one that has existed likewise in past ages. Reviewing the signs of closure of the naso-pharyngeal cavity as expressed in the physiognomy, he showed that these consist in the habitually open mouth, the laterally compressed nose resulting from the perma-

FIG. 1.—Young Greenlander, from Arznk, with Adenoid Vegetations.

nent inactivity of the alæ, and a sort of veiled look about the eyes due chiefly to an elevation of the under lid. This appearance of the eyes is that which characterizes all of Fra Angelico's saints. Another objective symptom of the affection and one that forces itself upon the attention of even the most unobservant of the laity, is the altered tone of the voice, the so-called nasal twang, the absence of resonance, and the faulty enunciation of the sounds of m and n.

When once the significance of these symptoms had been pointed out and it had been shown that the presence or absence of adenoid vegetations could be determined with certainty by means of digital exploration, these growths were very generally found wherever they were looked for. It was learned that not only in countries like Denmark, with a damp, raw climate, but also in all other parts of Europe, the affection was widespread. Statistics were quickly collected with a view to determine the relative frequency of the condition in different countries. The first of these were based upon the phonetic method of investigation, school children being made to utter a certain word or phrase containing the letters m and n, the inability to pronounce these letters distinctly being regarded as an indication of the presence of adenoids. This method commends itself by reason of its ready

applicability and its simplicity, no special skill being required of the examiner. It is, however, applicable only to the collection of gross statistics, being too un-

FIG. 2.—Young Malay, from Amboina, with Adenoid Vegetations.

reliable to be depended upon when more than an approach to accuracy is desired. A second method is that of digital exploration, which is, of course, much more accurate but at the same time slower in its execution and troublesome to both examiner and examined. A third mode, but one which despite its accuracy is impracticable for the collection of extended statistics, is that of direct inspection through the rhinoscopic mirror. The result of investigations undertaken by one or other of these methods has shown that hypertrophy of the pharyngeal tonsil is a very common condition among those of the Indo-Germanic races. But other branches of the human family are also subject to the affection. Of sixty Greenland children from six to fourteen years of age, examined digitally by Dr. Helms, only sixteen (26.7 per cent.) were found to be free from adenoid vegetations. Of those affected twenty-three had the typical adenoid facies, as shown in Fig. 1. If one were justified in drawing any conclusions from such a small number of cases, one would say that adenoids occur in Greenland with a frequency unheard of in Europe. Among the North American Indians also reports show that hypertrophy of Luschka's tonsil is of very common occurrence. We do not need the author's assurance to convince us that adenoids are common enough in the United States, and Dr. Tidemand, of Montevideo, states that they are of not infrequent occurrence among South Americans of European descent. Statistics concerning the aborigines of that continent are wanting.

In Hong-Kong Dr. Cantley states that the affection is very common among the pure Mongolians as well as among the half breeds. In Siam, Sumatra, and other parts of southeastern Asia, sufferers from adenoid vegetations are constantly found, though in smaller number than in northern Europe. Fig. 2 shows the adenoid facies in a young Malay. In clos-

ing this part of his investigation Dr. Meyer concluded that adenoid vegetations are found in varying frequency in at least three continents, viz., Europe, Asia, and America, although a warm climate seems to favor hypertrophy of the pharyngeal tonsil less than does a cold climate.

It is very improbable, as the author says in opening the second part of his subject, that a pathological condition so universally distributed as adenoid vegetations should be of recent origin, yet the difficulties in the way of proving its prevalence in former times, before the existence of such a condition was known or suspected, are, of course, very great. In the search for evidence bearing upon this point we have only two sources upon which to draw, namely, written documents and plastic or painted portraits of individuals. It is evident that little can be gleaned from reports, since there would of course be none of adenoids as such, and we can only pick out from the reports of cases the descriptions of individual symptoms now recognized as those of hypertrophy of Luschka's tonsil. Again, in the search among human documents for the typical adenoid facies we must be careful to avoid certain sources of error. For example, portraits which are intended to express emotion, especially religious ecstasy, and those of people with a short upper lip or with projecting teeth, might lead us to imagine that the subjects were mouth breathers. In order to avoid this error it is better to study only faces which are in repose or those of important personages of whom several portraits are in existence. Of course, this narrows the available material down to very small limits. Yet we need but few positive instances of the

FIG. 3.—Antonio Canova (painted by himself).

kind to establish the fact that the existence of adenoid vegetations dates back to more or less remote periods.

The first case established by the writer is that of Canova (1755-1822). Of this celebrated sculptor many portraits and busts are in existence, one of which, an excellent vignette in Cicognara's "Biography of Canova" (Venice, 1823), is reproduced in Fig. 3. All these show an open mouth and narrow and laterally compressed nostrils; many show also the veiled appearance of the eyes. It is safe to assume

that no artist would delineate a subject, especially himself, with open mouth if he could truthfully avoid it, and it seems quite certain therefore that Canova was an habitual mouth breather—an assumption that is strengthened by the shape of the nose. That this was the result of adenoid vegetations is rendered highly probable by the fact, which is given on the authority of one of Canova's pupils, that the master was deaf.

Going still further back we find the Emperor Charles V., of whom it can be said with great probability that he too had adenoid vegetations. His physiognomy is familiar to all and offers a typical example of the adenoid facies. In all his portraits we have the same open mouth, laterally compressed nostrils, and veiled look. The explanation of the open mouth of Charles V. has usually been the projecting lower jaw and the thick under lip of the Hapsburgs, but Dr. Meyer believed it to be an indication of adenoids. In proof of this is the fact that his brother Ferdinand I. also had the adenoid facies, but especially confirmatory are the indications of a gradual disappearance of the hypertrophy furnished by the successive portraits of the emperor from childhood on through youth to adult life. We are told also that Charles V. had a peculiar pronunciation of certain words so that it was sometimes difficult to understand him. Vesalius, the emperor's physician, states also that his illustrious patient suffered from asthmatic attacks—a fact of little importance taken by itself, but one that lends much weight to the adenoid theory when taken in connection with the other evidences.

Francis II., of France, who died in 1560, was also apparently a sufferer from adenoids, although his portraits present none of the characteristic features of the adenoid facies. Potiquet argues that this was the case, as he finds from contemporaneous records that Francis was a mouth breather, spoke with a nasal intonation, and had a chronic otorrhœa.

Another proof of the existence of hypertrophy of the pharyngeal tonsil is that the artists of the Renaissance have often depicted a typical and unmistakable adenoid facies in their paintings and sculptures. For example, in a painting of Ghirlandajo in the Uffizi collection there is a man in the crowd with a typical and pronounced adenoid face, and in the Copenhagen Bourse there is a stone head among the decorations in which all the external signs of hypertrophy of the pharyngeal tonsil are evident. It is highly improbable that artists would have depicted such faces had they not been common types.

The remains of antiquity present few evidences of the existence of hypertrophy of Luschka's tonsil among the ancients, yet there are some heads presenting the typical adenoid facies. The author found three in the Museo Chiaramonti in the Vatican. No. 80 is the head of a ten to twelve year old boy. The nose is restored, but the mouth, the eyes, and the half-stupid, half-resigned expression of the face point clearly enough to the fact that the boy had adenoids. No. 189 is an artistically executed head of a three or four year old boy with the characteristic facies. No. 192 is the bust of a young lady of the upper classes, as evidenced by the drapery and the carefully dressed hair. This face is regular, with good features, but is somewhat disfigured by the partly open mouth, looking as if air were being drawn in, and by the veiled look about the eyes. The two boys' heads are apparently portraits, while the woman's head is regarded simply as an ideal; but that signifies nothing, since even for an ideal head the artist must have had a model and must have presented a type of what was seen in life, that is to say, a sufferer from adenoid vegetations.

Thus, the author concludes, it has been shown that

adenoid vegetations are found among the inhabitants of at least three continents, and that there have been sufferers from the affection during the greater part of the historical era. The subject was one of peculiar interest to Danes, since it was in their country that the condition was discovered and first accurately described.

Post-Influenzal Pericranial Effusion.—Dr. Wynter exhibited before the Harveian Society of London, March 5, 1896, a case of pericranial effusion following influenza. The patient, a man aged thirty, had influenza at the end of January, 1896. About a fortnight later he noticed seven or eight tender bumps on the head, situated over the brow, temples, and vertex, about the size and shape of half a hazelnut, and in the first instance almost as hard as bone. After three weeks some had nearly disappeared, the others fluctuated and were evidently fluid. They were firmly fixed to the bone and the scalp moved freely over them. There was no redness and no history of syphilis. Dr. Wynter quoted two other cases he had met with in the spring of 1895 in a man and woman, both aged fifty. In the latter one bump had suppurated and the condition recurred with a subsequent attack.—*British Medical Journal*.

Treatment of Epithelioma.—Dr. Dumontpallier, writing in *La France Médicale*, March 13, 1896, relates a number of instances in which tumors of the mouth have been improved under the use of solutions of chlorate of potassium. Several cases of ulcer of the tongue which appeared to be of epitheliomatous nature healed under this treatment. Internally the patient is given daily a mixture containing four grams of chlorate of potassium in one hundred and twenty grams of distilled water, and four times daily he applies the same drug in fine powder freely over the whole tumor. The kidneys must be examined before these large doses to make sure there is neither albumin nor sugar present. His first patient had been previously operated upon without lasting result, but has now been well eleven months since the above treatment was carried out. In the second case the ulcer has cicatrized and treatment is being continued.

Treatment of the Gravest Forms of Cardiac Dilatation.—Sir Dyce Duckworth, according to *The Practitioner*, says that in a large majority of cases venous engorgement, anasarca, nausea, gastro-enteric catarrh, etc., are coincident with and dependent on the dilatation of the cardiac cavities. Such patients are admitted into hospitals *in extremis*, too ill even for examination; a physiological diagnosis shows what is necessary to be done at once. The heart beats tumultuously, no murmurs can be detected, the two sounds closely resembling each other. We can almost certainly predicate mitral stenosis. The prime necessities are rest, adjusted pillows, warm bed, and warmth to the feet. Large doses of spiritus atheris compositus are exceedingly useful. Forty to one hundred minims may be given every three hours in an ounce of camphor or peppermint water. An excessive lividity of the surface or turgescence of the jugular veins demands venesection. The symptoms may be distinctly relieved by the removal of not less than six nor more than ten ounces of blood. In lieu of venesection one may place six or ten leeches over the precordia. Subsequent examination will reveal anasarca, swollen liver, etc. The tumultuous action of the heart having subsided, we may find dilatation superadded to hypertrophy, with pericardial or pleuro-pericardial adhesions. In a few days we may find marked improvement in response to rest, careful diet, saline aperient (mistura sennæ composita, one to one and one-half ounces, with tinctura jalapæ, one drachm), with occasional doses

of citrate of ammonium and potassium. It is wisest not to give digitalis during the tumultuous heart action. A feeble, irregularly acting heart, with a feeble fluttering pulse, demands digitalis. Ten to twelve minims of the tincture of digitalis three or four times daily will prolong the diastole and make the heart steady and regular; not infrequently a free flow of urine and a subsidence of the dropsy supervene. In many cases, after a return to the usual conditions of life, a relapse occurs. The same measures may again succeed, but often benefit is derived from restricting the amount of fluids in cases of dropsy (of cardiac origin) and a pill of two grains of bluepill with one each of powdered digitalis leaves and squill. Two or three ounces of brandy or gin in twenty-four hours, given in milk, are very useful. The hepatic engorgement is greatly relieved by the mercurial pill. Persistent dropsy occasionally requires puncture. Dyspnoea and insomnia are best relieved by morphine. Paraldehyde is also useful. Constipation is best treated by drachm or half-drachm doses of compound jalap powder in milk. A diuretic drink is lemonade, to which bitartrate of potassium, one drachm to the pint, is added. Easily digestible and nutritious diet should be given—tender mutton, meat, fowl and fish finely minced, milk, eggs, broth, and custard pudding; cocoa and coffee, toast and rusks, potatoes well mashed, and spinach. In the majority of cases digitalis is the best drug. Strophanthine is useful when digitalis is not well borne. Caffeine in four to five grain doses, combined with strychnine, is valuable. In cases with an aortic reflex digitalis must be guardedly used. The diastole may be prolonged too much for the left ventricle to bear. When the case is not under constant supervision it is best to rely on strychnine.

Bacteria and Milk.—That we may count upon microbes sometimes as our friends and sometimes as our enemies is well illustrated in the bacteriology of milk and milk products, says a writer in *The Lancet*. Though milk may leave the udder perfectly sterile, yet a few moments of contact with the air, and especially the air of insanitary surroundings, are sufficiently long to be the starting-point of the development of a whole microbial menagerie. By fissure alone—that is, by splitting in two, and by the resulting two dividing again in the same way—one bacterium may become the parent of over sixteen million bacteria in twenty-four hours. The composition of milk is such as to be most favorable to the growth and development of organisms, pathogenic and non-pathogenic. Some are detrimental to the healthy condition of the milk itself, or, in other words, milk has its own diseases to contend with. Experience is ever teaching how imperative it is that the strictest care should be taken to protect milk against the possibility of microbial invasion. The risks of pollution are great, and may arise from an unhealthy or dirty condition of the cow, or of the stall, or of the milker's hands and clothes. The air of the cow house is frequently made insanitary by cleaning it out and dislodging dirt just previously to milking, and another source of contamination is the diluting of the milk with unwholesome water which may be infected with typhoid fever or cholera poison, or by placing the milk in dirty vessels, or by exposing it to the atmosphere of warm and unhealthy places, as cupboards. With these possibilities of pollution in mind the advantages gained by sterilizing or Pasteurizing milk by boiling are evident. Particularly is this so in the case of bottle-fed infants, the lives of many of whom would be saved from fatal diarrhoea, so frequent in artificial rearing, were these precautions taken. The same lesson is taught by the fact that mother's milk is sterile. Although boiling will destroy the disease-producing germs in milk, it may still

leave spore-bearing bacteria, which in course of time would produce undesirable changes in the milk itself and render it unwholesome. There are friendly germs to be found in milk whose functions can be cultivated and turned to account in the production of an acceptable flavor in cream and in butter. After clearing the milk or the cream of competing organisms by Pasteurism it is sown with a pure culture of lactic-acid-producing organisms. The flavor of the butter and, moreover, its keeping qualities being dependent upon the character of the souring process undergone by the cream preparatory to churning, a uniform product acceptable in both these respects may be obtained by proceeding carefully on these lines. The inculcation of these methods among dairy farmers would add an impetus to the milk-products industry.

Facial Paralysis.—Dr. Neumann (*Neurol. Centralb.*, October, 1895) says that the special liability of the facial nerve to be affected is due not so much to its exposed position, else the ulnar should often be affected, but to the large number of lymphatics and lymphatic glands surrounding it at its exit from the stylo-mastoid foramen. Stagnation of lymph would favor morbid changes in the neighboring nerve, and such stagnation would be particularly likely to occur at night; hence the frequency of nocturnal onsets.

Cocaine in the Eye.—Dr. Jackson (*Philadelphia Polyclinic*, December 28, 1895), says that when using cocaine to dilate the pupil for ophthalmoscopic work or for the determination of refraction in persons past fifty years of age, one must prevent drying of the cornea. Drying of the corneal surface will cause an irregular astigmatism that will cloud the view of the fundus. To prevent this one should use only so much of the drug as will be necessary (one drop of a four-per-cent. solution), and after its instillation keep the eye closed most of the time for fifteen or twenty minutes.

Treatment of Acute Rheumatic Endocarditis.—In the *Liverpool Medico-Chirurgical Journal*, Dr. Richard Caton describes the results of his treatment of rheumatic endocarditis during the last thirteen years. In that period rather more than three hundred cases of acute rheumatism have passed under his care, fifty-two of which developed endocarditis. In all the cases perfect rest, avoidance of exertion, and a light milk diet were adopted. The heart was examined daily and care taken to exclude from the statistics any cases of cardiac murmur not due to genuine endocarditis. In thirteen cases treatment was directed to the rheumatism only, no special remedies being employed for the cardiac complication; in one case the bruit disappeared spontaneously; in the others the lesion was permanent. These patients remained in hospitals for an average of twenty-eight days. The remaining cases were treated on a definite plan. As soon as the first indications of a bruit made their appearance, sodium or potassium iodide in ten-grain doses was given thrice daily in addition to the salicylates, and a blister the size of a florin was applied over the apex. As soon as the irritation of this blister began to subside a second was applied close to it; then a third, and so on—the patient being kept meantime as quiet as possible; exertion, exposure, and excess of nitrogenous food being strictly forbidden. A gradual subsidence of the bruit was frequently noticed in ten days. Of these thirty-nine cases twenty-nine were discharged with normal heart-sounds, ten with a bruit. This exceptionally good result may be in part due to prolonged rest, the average duration of hospital residence being forty-one days and of confinement to bed thirty-six days.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, April 4, 1896.

THE RECORD RAYS.

It is well after long striving and unremitting labor to note occasionally such indications of progress as may encourage continuance of effort and stimulate still more ambitious endeavors. In this view we doubt not our many readers will share with us the gratification of noting in the present issue the distributive power and the widespread influence of the MEDICAL RECORD, as demonstrated by the accompanying map of the world, on which are shown the route rays of their weekly visitor. There must necessarily be a feeling of satisfaction also on the part of writers and subscribers to know that individually and collectively they are so directly in touch with such a wide range of cosmopolitan intercourse. Such a condition of affairs would hardly be possible save with a scientific journal treating on subjects of living interest to mankind of all nations and having a practical application as broad as is humanity itself. With the constant interchange of direct and reflex influences, the widest and freest discussion of vital questions is made possible through a channel common to all and in the interest of all. This map pictures a realization of the actual against the imagination of the probable. It is a demonstration that not only is New York a natural medical centre, but that the RECORD is an efficient exponent of this fact. In touch with every nation and with the inhabitants of every clime, it joins all in the best of all missions—that of caring for the health and lives of every race; of giving to useful knowledge something of the characteristics of common property and making it practically available throughout the length and breadth of civilization. Although each ray represents a distinct route of transmission, it by no means indicates the actual numbers, sometimes amounting to hundreds and thousands, distributed along the lines traversing the different towns and cities here and abroad. If each line should represent merely an individual reader in a given locality, it would be necessary to make special maps of the larger cities on the same plan and would thus interfere with the more general schematic representation. To our many friends far and near we thus extend our cordial greeting, appreciating more than ever their substantial endorsement of our efforts and the grave responsibilities which attend the faithful discharge of a privileged duty.

THE SANCTITY OF PROFESSIONAL SECRETS.

It is a pity at this late day, considering the well-known confidential relations between physician and patient, that there should be any question as to the propriety or utility of divulging professional secrets. It is still more to be regretted that a physician holding an eminent position in London should stubbornly and foolishly set his opinion regarding the expediency or necessity of such action in direct opposition to that of every sensible man and woman in Christendom. The case in question carries the condemnation of its wrong answer on its face and needs only to be told to be appreciated. It appears that a year ago Dr. Playfair, of London, attended Mrs. Kitson, his sister-in-law, in consultation. The patient submitted to a necessary examination and a subsequent operation. As a result of the latter Dr. Playfair became convinced, inasmuch as her husband had been away from home for over a year, that the patient was not a faithful wife. She protested her innocence and begged Dr. Playfair not to tell his wife, nor her father-in-law, Sir James Kitson. Dr. Playfair refused to believe her statements unless she would admit that she had seen her husband within a year. She being unable to do this, the consultant not only cut off all communication with her but deliberately related what he believed to be the facts in the case to his wife and to Sir James Kitson. Sir James immediately thereafter deprived the patient of her annuity and she became a social outcast to her relatives. Mrs. Kitson then sent for her husband, who, believing in his wife's honor, instituted proceedings against Dr. Playfair for defamation of character.

On the trial the defendant did not attempt to plead the truth of his imputation, but sought to justify his action on the grounds that the facts were based on his honest belief and that his communication was privileged. The latter was the only issue involved in the case. He maintained that he had the right to protect his family against damaging associations with improper patients and without the knowledge or consent of the patients themselves. This view was also maintained by Sir John Williams, who specifically declared "that it was within the discretion of any of the twenty-three thousand physicians in England, on his own responsibility, to disclose a secret without consulting the patient, if he deemed it his duty for the protection of his wife or family or in the case of a crime." This moved the judge to inquire if he considered it the duty of a physician to inform the public prosecutor in case he found a patient had submitted to an illegal operation. Sir John replied that the College of Physicians had answered "Yes" to precisely that question.

"Then all I can say is," replied Justice Hawkins with some heat, "that it will make me very careful in the selection of my medical man."

In charging the jury the justice observed that if every medical man in the kingdom chose to betray a professional confidence under any given circumstance it would not alter the law, and that there were other means than those adopted for protecting the defendant's family.

"It would have been quite sufficient," continued he, "to request his wife not to be intimate with Mrs. Kitson, who had herself written him, saying that she would not cross his threshold until she had cleared herself, and especially as she had written him a pitiful letter, saying that the matter concerned only their two selves, and asked:

"Why did you not let my unhappy life go? I am hunted out like the veriest outcast. Do, for God's sake, err on the side of mercy and be my friend."

The doctor's reply was that he must close the correspondence, and that he would inform his wife the next morning.

Although leaving the questions both of fact and of privilege to the jury, the charge was clearly on the side of the plaintiff, with the resulting verdict of the enormous sum of sixty thousand dollars for the plaintiff. The verdict was received with cheers, the patient swooned, the defendant bowed his head to the stormy denunciations of an outraged community and to the bitter scathing of the astonished press. We repeat that it is a pity that one who by previous good work had won for himself fame in his profession should risk his good name, his self-respect, his sense of professional honor, his appreciation of justice to even the lowest of his patients, by such an unwarrantable and outrageous pretext. There is but one answer to the question as to whether or not professional confidences should ever be violated. Never, never, never. For those who do otherwise there is neither excuse nor argument. Nothing but silence and shame.

AN OPPORTUNITY FOR JINGOISM.

A CORRESPONDENT of the *Pacific Medical Journal* contrasts in a very striking way the difficulties which an American physician encounters who desires to practise medicine in Germany to those which a German meets who wishes to practise in this country. We all know very well that a German who comes here has, in most States, nothing to do but to put out his sign or perhaps have his diploma registered. Thus, he jumps at once into a more or less lucrative practice. They do things differently in the land of Kaiser William II. In the first place, an American who goes to Germany after he has graduated and received a degree in this country gets no credit for his degree, but only for the time he has passed in study. This is put to his credit on his university course. If he is beginning the study of medicine, he passes his nine or ten semesters, which mean four or five years of work, and then he receives his German degree. This, however, does not entitle him to practise. To do this he must pass the State examination, which requires a period of one or two years more. When he has done this he still is unable to practise medicine, because the government declares that no foreigner can practise in the German Empire. He must first, therefore, become a naturalized German citizen. But in order to do that he has got to serve three years in the army, so that altogether it is practically impossible for an American to go to Germany and practise medicine. We do not

know why any American should want to do it; still, as a matter of pure justice, it is not right that the privilege should be extended in the United States without any reciprocity. Nearly the same difficulties attend practice in France. The spirit of "jingoism," which is now so interestingly active throughout the country, might find a legitimate field to expend itself in this protective tariff against Americans.

IS SPECIALISM ON THE WANE?

A REPORT has gone abroad during the past year that in some of our larger cities the specialist has suffered in his practice out of proportion to the general practitioner. There seems to be no doubt that physicians in common with others have felt the effects of the financial depression under which the country has labored during the past two years, and it is quite probable that some workers in special fields have noted a palpable lightness in their exchequer.

There is, however, no reason to believe that there has been in any quarter a marked tendency to return to general practice by those well established in special lines. Owing to the rapid progress being made in medicine in general, it becomes more and more impossible for any man to acquire and maintain that degree of perfection in knowledge and skill in its application which will permit of his being regarded as a finished specialist in several branches at the same time. Obstetrics and gynecology naturally go hand in hand; the eye and ear make a good combination; the nose and throat are so closely connected in their pathological manifestations that they make quite proper and even necessary subdivisions of the broad field; while dermatology and the venereal diseases are so bound together by syphilis, with its untold cutaneous efflorescences, that no great objection can be raised to their being pursued conjointly by those whose opportunities have rendered them competent. Exclusive specialists are rarely found—not so those who would have it believed that they are "exclusive." To be sure, a man who practises outside of his chosen branch does not and cannot, as a rule, have the same support from his *confrères* as he who confines himself strictly to his own line, but in times of depression he has two strings to his bow, and an epidemic of diphtheria may help him out when his anteroom is no longer overflowing with ladies waiting to have their tubes removed. A specialist does not always have the "cinch" he is often presumed to enjoy. In many ways the matter has been overdone or has become too refined. Good, old-fashioned family practitioners are too few, and without them no special branches can exist. When every one becomes a specialist chaos reigns. When men start upon their careers as specialists without that experience in general medicine which practice alone can confer, they are starting upon a road which surely leads to the discredit of all true specialism. Specialists are never born. We would say to the student, whether or not you now have the idea of doing special work, ground yourself well

in pathology. If in after years you turn your attention to some particular branch of medicine, you will find this knowledge your best stock in trade. Without it your work will ever be on the upward incline. With it you can outstrip your competitor whose foundation was not so firm.

Choose the branch for which you find you have a particular liking, whose work is congenial, and for which your experience has particularly fitted you. Otherwise fit yourself thoroughly before you go into it, but once in work with zeal and courage and always with the end in view, not of getting rich, for few specialists even do that, but of leaving your chosen branch better than you found it.

In this way specialism will maintain the place it should have in scientific medicine, every branch will add to the general advance, and definite knowledge will increase much more rapidly than it ever could without the work of the specialist.

Let pseudo-specialism wane, but all credit and success to the honest worker in a narrow field of research.

News of the Week.

The Death Rate from Tuberculosis in Massachusetts is reported by the State Board of Health to be higher than in any other part of the world except certain restricted localities in Austria and Bavaria.

Chicago Physicians, under a new ordinance, can secure a permit and a badge entitling them to right of way in the streets when answering professional calls.

Examinations for Physicians in the Indian Service.—The Civil Service Commission has announced that the list of eligible candidates for the offices of physicians in the Indian service is entirely exhausted. The latest vacancy is at the Grand River boarding-school at the Standing Rock Agency in North Dakota. This is a \$900 per annum office, and there is no one available for the appointment. Civil service examinations for these places will be held in various cities on different dates from March 30th to May 20th.

He Blew Out the Gas.—One of six students of the West Penn Medical College blew out the gas in a hotel bedroom in Pittsburgh, Pa., the other night. All six students were sleeping in the room, and all came very near being asphyxiated.

Guy's Hospital is greatly in need of money and a subscription has been started under the patronage of the Prince of Wales in order to raise the desired £500,000.

Dr. T. K. Tuthill has been appointed a coroner in New York City by Governor Morton to fill the vacancy caused by the death of the late Coroner O'Meagher.

Dr. Theodore C. Heyl, a retired surgeon of the United States Navy, died in this city on March 21st. Dr. Heyl was born in Philadelphia in 1838. He was a graduate of the University of Pennsylvania and en-

tered the navy as an assistant surgeon in March, 1870. In 1874 he was promoted to passed assistant surgeon and was promoted to surgeon in 1881. In December, 1891, he was retired from the service on account of ill health.

Philadelphia Hospital. Drs. Augustus A. Eshner and Alfred Stengel have been elected to the medical staff of the Philadelphia Hospital, one of the most valuable clinical schools in the country and whose roll of physicians at different times has included some of the best-known names in American medicine. Both appointments may be viewed as civil-service promotions, each of the new incumbents having been for a term of years a registrar.

A National University.—The bill establishing a National University of the United States has been reported favorably by the Senate committee. It grants a charter to the university, provides for its government, grants it the ground in the city of Washington designated by President Washington as a site for a national university, and appropriates \$15,000 for the fiscal year ending on June 30, 1897, and \$25,000 for the year following.

Population of Greater New York.—It is estimated by Dr. Roger S. Tracy, of the Board of Health of this city, that the number of persons living within the limits of Greater New York is 3,195,059.

The Case of Dr. Kershner.—The President has approved the findings of the court martial against Dr. Kershner, who is thus dropped from the roll of the medical department of the navy. Our readers are already informed of the circumstances of this celebrated case. After thirty-five years of service he is now deprived of his rank and sacrificed to technical charges which would not be entertained outside of a court martial. It is the old grievance of the line against the staff, and should stimulate every ambitious medical man to try his luck in the navy. There is one more vacancy.

Philadelphia County Medical Society.—At a meeting of the Philadelphia County Medical Society on March 25th Dr. M. H. Cryer presented by invitation a number of interesting lantern slides, illustrating various normal and pathological conditions of the maxillary bones and their adnexæ and prepared from actual dissection. Among other things he pointed out that the natural orifice of the antrum of Highmore is situated at the upper and inner angle of this cavity, so that spontaneous drainage could scarcely take place in the ordinary erect posture. He also contended that from the situation of this orifice and from its protection by a valve-like covering it would not be possible to enter it with a probe through the nasal cavity. Certain interesting peculiarities in the relations between the antrum and the infraorbital nerve on the one hand and some of the teeth on the other hand were also demonstrated. Dr. G. Hudson Makuen detailed an account of "An Unusual Alveolar Abscess with Antral Complications," the pus collection forming in the periodontium. The antrum was entered by

misadventure and underwent suppurative inflammation, but all of the symptoms abated as soon as the offending tooth was removed. Dr. John B. Roberts reported "Cases of Artificial Anus and Fæcal Fistulæ Successfully Treated by Intraperitoneal Operation," three in number, in which the infirmity was corrected by opening the abdomen and performing enterorrhaphy. Dr. H. F. Hansell read "The Report of a Case of Sudden Blindness from Nasal Disease," in which a lad after sleeping on the floor was found to have lost vision in both eyes and to present symptoms of ethmoiditis. The opinion was held that there resulted coincidentally or secondarily a meningitis about the optic chiasm or perhaps a retrobulbar neuritis. Central light perception remained entirely absent, although there was some return of vision in the remainder of the field.

Skiagraphy.—Dr. Abbott, surgeon at St. Thomas', London, believes that he has been the first to succeed in causing the "X" rays to penetrate through the entire thickness of the body. The *British Medical Journal* of March 14th contains a skiagraph of a case of tuberculous disease of the hand with extensive involvement of the forefinger, illustrating the possibilities offered by the new discovery of localizing with great exactness the position and extent of necrotic areas of bone. Dr. Pinard has presented at the Paris Academy of Medicine skiagraphs of a fetus within the uterine cavity from a specimen which has been preserved in alcohol for six months. Experiments have led to the belief that the uterine wall in life will permit of the same power of penetration as when hardened in the laboratory. The movement of the living child might, however, interfere with its being "taken."

It is Untrue that by the Roentgen method anatomical diagrams are reflected directly upon the brains of students in one of our medical schools, thus doing away with the necessity of hard work. We would inform students who might be attracted to this school by such claims that any impression left upon their brain cells by the details of anatomical structure will have to be made in the good old-fashioned way in vogue before the time of the Roentgen ray.

Repeal of the Suicide Law.—A bill has been introduced into the legislature of this State revoking the penalty for attempted suicide. The law at present in force inflicts a punishment upon the man who fails to destroy himself satisfactorily.

Destruction of a Hospital.—A fire, due to the carelessness of a plumber, destroyed the Church of St. Sauveur at Lille, France, on Sunday. The adjoining hospital was also burned. Four patients in the hospital died of fright before they could be removed. Ten firemen who had been ordered to save the medicines drank what they supposed was liquor, and were poisoned, four of them dying soon afterward.

Practical Opposition to a Hospital.—Two hundred residents of Grand View, a suburb of Kansas City, Mo., recently demolished the framework of a pest-house which was being put up for the uses of the Kansas City health board.

The Water Supply of Philadelphia.—With characteristic wisdom the City Councils of Philadelphia have defeated an ordinance looking toward the filtration of the water supply, in the face of a demand for some such improvement emanating from the most important, most respected, and most intelligent elements of the community. Reliable statistics show that while both the prevalence and the fatality of typhoid fever in Philadelphia have diminished in recent years, the number of cases per hundred thousand of inhabitants is much larger than in the city of London, and it is perfectly evident to all thinking and observing minds that this high morbidity is directly attributable to the quality of the water supply.

The Buffalo General Hospital, one wing of which is now in process of construction, will be a handsome building when completed, to judge from the plan given in the annual report, just out.

Foreign Physicians in Paris number 521 out of a total of about 3,000. It is said, however, that only 250 or thereabout actually practise.

Compressed Gas in cylinders exposes physicians, nurses, and patients, as well as all who handle them in transportation, etc., to constant danger, as shown by a recent explosion in England. A committee appointed to investigate the whole matter reports that official inspection of gas cylinders is required.

University of Pennsylvania Scholarships.—Twenty-seven new scholarships and fellowships of an aggregate value of \$13,200 are announced by the University of Pennsylvania as arising from the George Leib Harrison Foundation for the Encouragement of Liberal Studies and the Advancement of Knowledge. Eight scholarships, each of the value of \$100 a year and free tuition, open only to graduates of the university. Fourteen fellowships, each of the value of \$600 a year, less \$100 for publication or equipment, open to graduates of any institution, may be held for two years, and are intended for candidates for the degree of Ph.D. Five senior fellowships, each of the value of \$800 a year, may be held for three years, and are open only to those who have taken the degree of Ph.G. at the university. These scholarships and fellowships represent a part of the income derived from the recent munificent gift of \$500,000 made by Charles C. Harrison, the provost of the university, in honor of his father.

The Climate of San Diego.—The records of the United States Signal Service at San Diego, Cal., show that during twenty-two years, from 1872 to 1894, out of 8,035 days, 7,445 were clear or fair. During nineteen years, from 1875 to 1894, out of 6,936 days there were 6,723 days in which the temperature did not rise above 80 degrees and only two days in which it fell to 32 degrees.

Hospitals for the Treatment of Tuberculosis.—In Germany a number of special hospitals for consumptives have been recently established at Bremen, Breslau, Dresden, Hanover, Cologne, and Frankfort-on-Main, and in Berlin it is proposed to erect two as soon as the necessary funds are secured.

The Late Dr. Alex. S. Hunter.—The special committee of the Medical Society of the County of New York to prepare resolutions on the death of Dr. Alexander S. Hunter, offered the following:

"The Medical Society of the County of New York hereby records with profound sorrow the lamented death of its fellow-member, Dr. Alexander S. Hunter, which took place February 14, 1896, at his residence at Spuyten Duyvil, New York City.

"Dr. Hunter was twice elected to the office of president and for many years was a member of the board of censors; under his wise guidance and through his judicious counsel the Medical Society of the County progressed in honor and maintained its prosperity to a marked degree.

"A genial friend, thorough student, a careful diagnostician, a faithful physician, the society and the community have suffered an irreparable loss.

"*Resolved*, That a copy of these resolutions be published in the medical press and also transmitted to the family of the deceased.

"HENRY E. CRAMPTON,

"DANIEL LEWIS,

"JOHN S. WARREN,

"Committee."

The Medical Association of Hawaii, which has been formed since the establishment of the republic, is intended to constitute the representative body of the regular profession of the Sandwich Islands. Its meetings will be held in May of each year, the time and place being announced by the secretary in the February or March preceding. The society has adopted the code of ethics of the American Medical Association as its guide and watchword, the code having "the full force and effect of an article of the constitution, in part or as a whole."

The New Orleans Medical and Surgical Journal passed with the March number under the editorial charge of Drs. Chassaignac and Dyer. We wish the new editors all success in maintaining the excellence which has characterized the management of this journal in the past.

The Practice of Medicine in New York.—The field for the practice of medicine in New York City is not a desirable one. The profession is overcrowded in the medical Mecca of America, and it is to be yet more crowded. Dispensaries are increasing and their influence for evil upon the profession of the city is enormous. The post-graduate schools, originally of value to the members of their teaching corps, have made specialists all over the country, who have cut off much work which formerly went to New York from the doctors of the interior. Yet, in the face of all these oppressing facts, for the man of marked ability, deep learning combined with genius, New York is still the first city in the land. One has but to look over the progress of a half-dozen or a dozen of the leading lights of New York to see that by a few successes in large abundance, even under present circumstances, can be attained in that city.—*Medical Sentinel*.

A Memorial to Prince Henry of Battenberg, in the shape of a sanatorium for those debilitated by African fevers, is proposed. It has not been decided whether to locate it on some elevated portion of the mainland of Africa or on Grand Canary Island.

Bathing in Typhoid Fever.—The editor of the *Medical and Surgical Reporter* does not believe in cold bathing in typhoid fever, therein agreeing with many other physicians, and he also does not hesitate to give expression to his disbelief: "If the fact that a typhoid patient is too hot is sufficient cause for sousing him in cold water," he says, "why shall we not also relieve a starving man by a liberal allowance of food, and revive a man dying of thirst by unlimited amount of water internally? 'Look at the increased renal elimination,' triumphantly shouts the immersionist, who uses the bath not to reduce temperature but to improve phagocytosis and nutrition. He overlooks the fact that his treatment checks perspiration, drives the blood from the skin to the already congested and poisoned viscera, and leaves only the choice between diuresis, diarrhoea, and death. There is no doubt that cold bathing does stimulate phagocytosis and other vital processes of which our knowledge is still more indefinite, but only in healthy or simply depressed systems. Yet the evil effects of injudicious use of this and similar hygienic means in persons not quite resistant enough is too well established to require more than the briefest allusion. The immersionists plunge almost every case of typhoid that comes into their ward, including anæmic girls, flabby women, debilitated men, for whom cold bathing would be prescribed with the greatest caution (not more than twice daily) if they sought advice for the general conditions of weakness uncomplicated by typhoid. Even if we grant that the existence of typhoid is not so important a contraindication of cold bathing as many comparatively insignificant constitutional states, must we also admit that in patients having both the dyscrasia and the infectious disease the latter has conferred an immunity, and that they are, so to speak, above par in resistance because of the infection and elevation of temperature?"

Buried Alive.—An army surgeon asserts that very many of those who are supposed to be dead are really buried alive, and he recommends that a bottle of chloroform be buried with the corpse in order that its escaping fumes prevent a return to consciousness and a realizing sense of the horrors of being immured in a coffin beneath the ground. We would suggest cremation as a better preventive of revival than chloroform.

The Medical Department in the British Army is becoming very unpopular by reason of the systematic snubbing which army surgeons receive from their fellow-officers of the line and from the authorities in the war department. While formerly there was very active competition among young surgeons for commissions in the army medical service, it is now almost impossible to fill the vacancies. The same trouble exists in this country in the naval medical service.

Reorganization of the State Lunacy Commission.

—The following amendment to the pending lunacy bill is proposed by THE MEDICAL RECORD:

SECTION 2. There shall continue to be a State commission in lunacy, consisting of one commissioner from each State hospital district, all of whom shall be citizens of this State. The commissioners from the following districts: viz., from the Long Island State Hospital district, from the Manhattan State Hospital district, and from the Buffalo State Hospital district, shall be reputable physicians, graduates of an incorporated medical college, and of at least ten years' experience in the actual practice of their profession. Within twenty days after the passage of this act, the Governor, by and with the advice and consent of the Senate, shall appoint said commissioners and shall designate their respective terms of service, as follows: viz., one medical commissioner to serve two years, one to serve four years, and one to serve six years; two of the commissioners who are not physicians to serve one year, two for two years, two for three years, and two for four years. Thereafter each appointment shall be as follows: For the medical commissioners a term of six years, and for the non-medical commissioners a term of four years, except when an appointment is made in either class of commissioners for an unexpired term, when the appointment shall be for the remainder of the term. Said commissioners shall be entitled to receive as compensation ten dollars per diem for each day's attendance upon the meetings of the commission, but the total amount received annually by any one commissioner shall not exceed five hundred dollars. Said commissioners shall be entitled to receive their actual and reasonable expenses while engaged in the performance of their duties. Said commissioners shall meet at the rooms of the Lunacy Commission at the Capitol, on the first Wednesday of June next, and organize by the election of a president, and of a secretary who shall not be one of their number. Thereupon the commission created by this act shall succeed to all the powers, duties, and privileges conferred upon and exercised by the former State commission in lunacy by virtue of any law or laws, and shall take, hold, and possess all records, documents, books, and other property, of whatever name or nature, in the possession of said commission.

The Medical Profession in Belgium.—According to statistics recently published, the number of physicians in Belgium at the beginning of the year 1895 was 2,956. The proportion of doctors to population was 1 in 2,100. In addition to these there were 2,394 midwives, 1,828 pharmacists, and 522 veterinarians.

A Solemn Fact Solemnly though Tardily Expressed.—The introduction of such drugs as chloroform and ether and their adoption as means of rendering the patient insentient and passive during the performance of even the most complicated operations have added one more to the grave responsibilities which surround the medical practitioner of to-day.—*The Lancet*, March 7, 1896.

The Intercolonial Medical Journal of Australasia is the title of a new journal published in Melbourne and formed by the amalgamation of the *Australian Medical Journal* and the *Intercolonial Quarterly Journal of Medicine and Surgery*. It has no lack of editors, the names of no less than seventeen appearing on the title page of the first number. The receiving editor, to whom communications should be addressed, is Dr. David Grant, of Melbourne. The initial number, dated January 20, 1896, gives promise of an excellent journal and we wish the new venture all prosperity.

The New York State Medical Association.—Members of this society who intend to read papers at the next annual meeting in October are requested to send the title of such papers to Dr. E. D. Ferguson, Troy, or Dr. J. G. Truax, 17 East Twenty-Seventh Street, New York City.

Dr. Ostrowmoff, professor of clinical medicine at the University of Moscow, has received from a resident of that city the sum of \$200,000 for the erection of a hospital for the treatment of purely medical cases. The donor has forbidden the disclosure of his name.

A Homœopathic College in Mexico.—President Diaz has recently signed a decree authorizing the establishment of a homœopathic medical college in Mexico City. There will be a five-years' course of study, and the faculty, composed of homœopathic physicians, will be appointed by the government.

The Language Question at Moscow.—The St. Petersburg correspondent of the *British Medical Journal* says that the regulations of the Moscow International Congress, excluding the use of English, have caused so much dissatisfaction that one of the secretaries of the congress, Professor Diakonoff, has thought it necessary to address a long letter of explanation to the *Traveller*. The writer says that the inconvenience of polyglot discussions had become so marked at international conferences that the medical press of all countries, after the Rome congress, recommended that one official language be chosen for future congresses, and all pointed to French as the best for the purpose. The rules which the organizing committee of the next congress has adopted were drawn up by the medical faculty of Moscow University. In drawing them up the faculty felt bound to act on the opinions so generally expressed in the medical papers. Consequently, it at first decided to make French the one official language of the congress. Later it appeared necessary to admit the use of Russian, although "from a feeling of delicacy to our foreign guests, of whom few could know Russian," it was decided to employ that language as little as possible. Still later the fact that more Russian medical men go to German universities than to French, and a great many understand German and are ignorant of French, was taken into consideration, and therefore German was admitted to the sectional meetings. "But," the letter continues, "in thus admitting two foreign languages, we cannot hide from ourselves that we have

departed from the principle of a single language—albeit from necessity—and we recognize that in future efforts must be made to return to that principle in all its purity.” This is the present stage of the language controversy. If the regulations as they now stand continue to hold good, there will be no possibility of reading English papers or of discussing in English in any of the sectional meetings. It will only be in the three general meetings that Englishmen or Americans who are unable to speak either French or German will have a chance of speaking at all. But as no discussions are permitted at the general meetings, this is equivalent to an intimation that “no English need apply.” Dr. Diakonoff’s explanation is ingenious but not ingenuous, and was probably not intended to be believed.

Diphtheria Antitoxin in Japan.—There were 353 cases of diphtheria treated by serum injections in Tokio during the year ending November 25, 1896. Of this number 31, or 8.78 per cent., died. In the statistics collected by Kitasato of 26,521 cases of diphtheria in Japan, treated before the introduction of orrotherapy, the number of deaths was 14,996, a mortality of 56.54 per cent.

Rectal Orrotherapy.—Dr. Chantemesse, of Paris, advocates the administration of antitoxin serum by rectal injection instead of subcutaneously. He has used this method in twenty cases, and believes that the fluid is easily and quickly absorbed. The bowel is first washed out by a simple enema, and then by means of an ordinary enema syringe and a gum-elastic catheter of medium size and about twenty centimetres long the serum is introduced into the rectum. The method causes neither pain nor any other unpleasant effects. The curative effect seems to be as certain as when the antitoxin is given by hypodermic injection. There is no need, so far as Dr. Chantemesse’s experience goes, for any increase of dose when the serum is administered by the rectum.

The Effete East.—The medical institutions of the Atlantic seaboard are not so good as, or at least no better than, they are in Cleveland. Dr. Parker has been visiting them and writes to the *Cleveland Medical Gazette* that “they have some palatial operating-rooms at the Roosevelt and Presbyterian hospitals and many others not so palatial, but in each are found the same operating-furniture, instruments, and appliances as we have at home. One surgeon and his assistants stamped about in wooden shoes, another surgeon and his assistants wore canvas shoes, and still another operator made a complete change of his clothing after each operation. Perfect asepsis does not depend upon such non-essential details. Indeed, there is great danger that in carrying out these non-essential details the principles of clean surgery may be overlooked. Asepsis is not secured by wearing wooden shoes or canvas shoes, and there are various ways of rendering the hands surgically clean.” At the Johns Hopkins Hospital the chief peculiarity was the use of silver wire for sutures and silver foil for protection immediately over the wound. The writer

observed numerous instances at this hospital of the violation of aseptic principles. Philadelphia medical schools seem to be very much behind in the procession. “At one of the Philadelphia schools the professor of surgery spoke very enthusiastically of what he was pleased to call his method of teaching surgery. He divides his class into sections, and each section attends the surgical dispensary every day one hour for a few weeks, examining the cases presented and assisting in the minor operations performed. This is certainly an excellent method of giving instruction, but it is just what we do for the entire term. At one of the schools I sat with over four hundred students in a most filthy amphitheatre through a lecture upon fractures of the elbow-joint. There was an ill-concealed impatience among the students; so boisterous did they become that the lecturer twice stopped in his discourse and begged in supplicating manner that they desist and permit him to finish his lecture. And this was no fault of the lecturer, for his talk was most practical and richly illustrated with numerous specimens, well-executed diagrams, blackboard sketches, splints, and dressings.” Finally, at all of the clinics there was a dearth of operation cases and a class in operative surgery could not be held, as there was no subject at hand.

Houston, Tex., has about one hundred and twenty-five physicians and they are still coming. A local journal intimates to intending newcomers that all the city will support are already located and at work.

A New Branch of Department Stores.—A Toronto daily paper says that there is to be established in a certain departmental store in that city a doctor’s office where consultation may be had for a quarter. The *Canadian Medical Review* asks with alarm if it is possible that in that city there is a medical man who would so demean himself and dishonor the profession as to value his work as a diagnostician and a medical adviser at a quarter per patient.

Roentgen Rays in Court.—The *Canadian Medical Review*, quoting from a Montreal daily paper, says that the Court of Queen’s Bench of that city will be the first court on record where Roentgen’s new photographic discovery will be used in evidence. A photograph of the leg of Tolson Cuning, who was shot on Christmas eve, will be filed, showing the location of the bullet. The photograph was taken by Professor Cox, of McGill University.

The Provincial Medical Journal ceased to exist at the beginning of this year, but another journal, *The Scalpel*, has been started by Dr. Dolan, the editor of the defunct journal, and gives promise in its early numbers of surpassing its predecessor in interest.

The Presbyterian Hospital of Philadelphia celebrated on April 3d with appropriate ceremonies the twenty-fifth anniversary of its organization. Among the events of the programme were addresses by Dr. S. Weir Mitchell, Provost Harrison, of the University of Pennsylvania, Dr. John Dewitt, of Princeton, Dr. Woods, and Dr. J. Addison Henry.

The Jenner Centennial.—The 14th of May next will be the hundredth anniversary of Jenner's first experiment in vaccination. The event will be celebrated by the American Medical Association in Atlanta a week ahead of time.

A Predecessor of Roentgen.—The method of photography reputed to be Professor Roentgen's discovery has been known and utilized by an Oxford professor for some time. Unfortunately for his fame, he never applied the method to the human body, devoting its use in research in mineral substances.—*The Hospital*.

A New Treatment for Colds.—Dr. Schnee is said to have cured acute coryza by a series of slight taps with a rubber hammer on the forehead just above the root of the nose. The theory is that slight shocks upon terminal nerves have the effect of contracting the blood-vessels.

Dr. Gwilym G. Davis has been elected surgeon to the Philadelphia Orthopaedic Hospital and Infirmary for Nervous Diseases, in succession to the late Dr. H. Ernest Goodman.

A Double Treat at the Terrapin Club.—The Terrapin Club of Philadelphia at its annual meeting on March 16th entertained Dr. S. Weir Mitchell, who made an appropriate and humorous address on the subject of terrapin.

Reception to Dr. A. Donaldson Smith.—Dr. Louis Starr, of Philadelphia, gave a reception at his residence on March 19th in honor of Dr. A. Donaldson Smith, the recently returned African explorer. Dr. Smith already speaks of resuming his explorations later on.

North Carolina Physicians are forced to pay a licence fee of \$10 per annum. The State is now asked to use the \$15,000 so obtained to establish and maintain a vaccine and antitoxin farm.

The Constitutionality of the Louisiana State Medical Law is about to be tested in a suit brought against the Board of Medical Examiners by two irregular practitioners whom it has endeavored to restrain from practice.

Dr. A. L. Metz has been appointed to fill the vacancy in the chair of chemistry at Tulane University caused by the death of Dr. Joseph Jones.

Cut Rates for Insurance Examinations.—The medical examiners in British Columbia for two of the larger life insurance companies of this city have been notified of a reduction of their fees to \$3 for all examinations under \$2,000. They have declined to make examinations at the reduced rate. A correspondent of the *Ontario Medical Journal* says that the *esprit de corps* is high in the medical profession in that province, and he predicts that the insurance companies will be unable to secure competent physicians to fill the places of the examiners who have resigned. The Sacramento Society for Medical Improvement has passed a series of resolutions protesting against methods which it characterizes as unfair, irrational, and

indefensible, and on behalf of its members pledging them to decline absolutely to examine applicants for life insurance for any "old line" company for any fee less than \$5 for each and every examination made.

Pay of Fire Department Surgeons.—A bill has been introduced into the legislature at Albany raising the pay of surgeons in the New York City fire department from \$2,000 to \$3,000 a year and giving them a pension as well. The surgeons to the police department get \$3,000 a year. There is also a clause in the bill which provides that a surgeon in the fire department shall not be dismissed except for cause.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the Medical Corps of the U. S. Navy for the week ending March 21, 1896: March 16th.—Surgeon P. M. Rixey ordered to the naval dispensary, Washington; Assistant Surgeon H. La Motte detached from the naval hospital, Chelsea, Mass., and ordered to the receiving-ship *Franklin*; Surgeon G. E. H. Harmon detached from the naval dispensary, Washington, and ordered to the Naval Academy; Passed Assistant Surgeon C. H. T. Lowndes ordered to the Washington Navy Yard.

Changes in the Medical Corps of the U. S. Navy for the week ending March 28, 1896. March 23d.—Passed Assistant Surgeon B. R. Ward detached from Coast Survey Steamer *Blake* and ordered to the *San Francisco* holding survey on Chaplain J. J. Kane in London en route. March 26th.—Surgeon J. C. Wise ordered to examination for promotion March 27th.

Raising Them out.—Having increased the term of study, some medical schools are making an effort to increase the requirements for admission. The University of Pennsylvania is among the latest of those pursuing this praiseworthy endeavor. It is suggested, too, that the tuition fee be increased. If any of these attempts at standard raising has the additional effect of keeping out embryos for a few years, the overcrowding in the profession may become less marked.

Two Hundred and Fifty Druggists Indicted.—A law and order league in Indiana has been busying itself with the sale of liquor in drug stores other than on physicians' prescriptions. Many proofs of violation of the law have been obtained and the campaign has resulted in the bringing into the circuit court of two hundred and fifty indictments against druggists.

The Tennessee State Medical Society will hold its annual meeting at Chattanooga on April 14th–16th. The preliminary programme contains thirty-five titles of papers and discussions and gives promise of a successful meeting.

Hot Springs.—According to Dr. Barry's article in the medical journal which bears the name of this celebrated resort, Hot Springs is the healthiest city in the world. The statistics of six consecutive years gives a death rate of 10.79 per 1,000 or 7.54 for the permanent residents alone.

The Dangers of Advertising.—Dr. Krause has resigned his position of privat-docent to the Berlin Medical University, owing to a difficulty with the faculty, who had asked him to give his reasons for allowing his name to appear at the foot of a testimonial for a certain brand of soap. On his refusal to do this, the faculty inflicted the severest reprimand in its power and he resigned.—*Boston Medical and Surgical Journal*.

Many Persons Frozen to Death.—During a recent snowstorm in the province of Oro, in Russia, one hundred and thirty persons were frozen to death.

Dr. J. Jameson has been appointed director-general of the medical department of the British army in place of Sir W. Mackinnon.

The Virginia Medical Monthly, after a long life of twenty-two years under the able editorial management of Dr. Landon P. Edwards, is now to become a semi-monthly. We congratulate our esteemed contemporary on this evidence of well-deserved prosperity and ever-increasing usefulness, and we hope that before another cycle of twenty-two years the *Virginia Medical Semi-Monthly* will become the *Virginia Medical Weekly*.

The Ohio State Board of Medical Examiners, recently appointed by the governor under the new law, consists of three regular practitioners, one homœopathist, two eclectics, and one physio-medical. What the belief and practice of the latter may be we confess we do not know.

The British Medical Association.—The next meeting of this association will be held in Carlisle on July 28–31, 1896. Mr. Henry Barnes, of Carlisle, is the president of the association for this meeting.

Public Health Officers in Germany must hereafter possess a practical knowledge of mental disease. The minister of education has issued an order which provides that candidates for this office will be required to attend a course of lectures on psychiatry at a German university and to attend the practice of a lunatic hospital for six months or to hold office as interne of such a hospital for three months. A hospital in which such lunacy practice is taken out must not have fewer than one hundred and fifty mental cases yearly. The order comes into force in October of the present year, and it will apply to all candidates who are not already in their last year of study.

Better Late than Never.—Now that the suppression of the Cuban revolution is rendered difficult, if not impossible, by reason of the decimation of the army of occupation by yellow fever, the Spanish government at Havana has appointed a commission to investigate the yellow fever of that island. The commission is composed of medical officers of the army and navy and of prominent medical men of Havana.

The Ohio State Medical Society will hold its fifty-first annual meeting in Columbus on May 27th–29th. The president of the society is Dr. Milliken, of Hamilton; the secretary, Dr. Thomas Hibbard, of Toledo.

The Medical Colleges of Kansas City, having refused to comply with the requirements of the Missouri State Board of Health, as a consequence have been dropped from the board's list of colleges in good standing.

The Missouri State Medical Association will hold its annual meeting in Sedalia, May 6–8, 1896.

The Medical Societies in Havana are reported to have suspended meetings on account of the unsettled condition of affairs on the island. The medical journals, however, still appear regularly.

The Canada Medical Record has passed under the control of the medical faculty of Bishop's College, Toronto. The editor-in-chief is Dr. J. B. McConnell.

A Little Mixed.—The *Denver Times* says: "Dr. George M. Gould has retired from the editorship of the MEDICAL RECORD, which is now being published in New York with J. Riddle Goffe as editor."

The Indiana State Medical Society will hold its forty-seventh annual meeting at Fort Wayne on May 28th and 29th.

Medical Men in the Cabinet.—According to the *Journal of the American Medical Association* the only medical man who ever served in the cabinet of the President of the United States was Dr. Oliver Wolcott, of Connecticut, who was appointed secretary of the treasury by Washington in 1795. Dr. Wolcott had served in the Revolutionary War and had risen to the rank of brigadier-general.

Cholera in Egypt.—There were one thousand and thirty-four cases of cholera reported in Cairo since last October, but of the entire number there was not a single one among Europeans.

The Overcrowding in the British Islands.—The British Medical Register for 1896 contains the names of 33,601 medical men—or one doctor for every 1,164 persons.

Gifts to McGill University.—W. C. McDonald, of Montreal, has given \$500,000 to McGill University for the purpose of providing a building for the study of chemistry, mining, and architecture. This brings his gifts to this university up to \$2,000,000.

The House of Detention, in which detained witnesses are kept, is said to be in a very insanitary condition, and the matter is now being investigated by the grand jury.

New York Veterinary College.—The twenty-first annual commencement of this college was held in Chickering Hall last week. There were twenty-six graduates.

Professor Mikulicz, of Breslau, has been seriously ill, but after a stay of several weeks at Abbazia is now, we are glad to learn, entirely restored to health and has resumed his work at Breslau.

A Case of Varicella.—A woman living as a domestic in Brooklyn was recently taken ill and sent to the Reception Hospital as a suspected case of small-pox. After a short stay there she recovered, and it was concluded that the case was one of chicken-pox.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 7, 1896.

ANDREW H. SMITH, M.D., PRESIDENT, IN THE CHAIR.

BEFORE presenting the case which follows Dr. SEXTON said that the case of deafness due to sclerosis which he presented at the December meeting was operated upon a few days later. Before this the patient could scarcely hear anything spoken close to the ear. After the operation she could hear an ordinary tone of voice four or five feet away.

A Case of Twelve Years' Standing of Purulent Discharge from Both Ears, with Great Deafness, Speedily Cured by Excision of the Diseased Structures in Both Drums.—Dr. SAMUEL SEXTON presented a girl aged fifteen years, who had had a discharge from both ears consequent on an attack of measles, accompanied by great deafness, since she was two years old. A sequestrum came from the right mastoid at the start. The membrana tensa and a narrow rim of the membrana vibrans on either side held the remains of the malleus, which interfered with drainage on both sides. She could hear an ordinary tone of voice in the right ear at less than two feet, in the left ear at six inches. She had been under the care of Dr. C. G. Stevens, of Watertown, N. Y., who, finding the case not to yield to ordinary treatment, sent her to me for an operation.

On November 26, 1895, the carious ossicles and diseased membrane holding them in place were removed under ether narcosis. From this time on the discharge became less and less and in a few weeks the drums were found to be healthy and dry. The hearing now is excellent; she can hear the voice in an ordinary tone from six to twenty feet away with either ear.

Attention is called to the mental inertia, so to speak, in this case due to long neglect in intellectual training. The patient often hesitates for some moments when spoken to before she is able to bring the mental apparatus into action and reply. This is one form of inattention and sometimes such wool gatherers forget what has been said to them before they formulate an answer.

Approves the Operation in Suppurative Cases.—Dr. BEVERLY ROBINSON had no hesitancy in saying that in suppurative conditions he believed the operation did good in many cases. An instance was the case just shown. Taking out carious bone from the ear cavity, allowing that cavity to drain properly, and putting it into the best possible condition, was a procedure which appealed to everybody's surgical intuition. For such cases the operation was known to result in considerable benefit, in the judgment of careful observers, and it was endorsed by a certain proportion of the most advanced workers in otology. He must confess that he was much more in favor of the operation in suppurative cases than he was in those of dry catarrh, where he thought it was of doubtful utility.

Dr. VIRGIL P. GIBNEY expressed his interest in the subject, and asked Dr. Sexton whether he made a distinction between dry and suppurative cases, as did Dr. Robinson. He would also like to know from him what was the status of the operation with otologists to-day.

Dr. JOSEPH D. BRYANT inquired what tissues were referred to as being associated with the disease process.

Dr. SEXTON replied that in suppurative cases there was usually great loss of the lower portion of the tym-

panic membrane—the membrana vibrans—while the upper portion which retained the malleus became thickened, retracted in some instances, but not often atrophied. The various folds of the membrane lining the attic and having reflections over the chorda tympani and ossicles formed a series of sacs sufficient to retain purulent and mucous matter constantly, so that the tympanic attic in which these parts were contained was scarcely ever free from mucus and purulent matter. A portion of this membrane in most instances went on secreting mucus, and with each head "cold" the patient had "gathering in the head," often accompanied by earache. Beginning in childhood, these gatherings often lasted well on to old age. Removal of the diseased parts, as in the case presented, resulted in cure. As could be seen, nothing remained in the tympanic cavity, and the very narrow edge of membrane adherent to the annulus tympanicus interfered in no way with drainage.

In reply to Dr. Gibney, he would say that he was as well satisfied with this operation in cases of "dry catarrh" as he was when he began it ten years ago, and even more so. But he was careful in the selection of his cases, and unsatisfactory results which had been reported by operators he thought were due to neglect in this direction. In some few cases it was to be expected that little was to be gained in the improvement of the hearing, but that little was important to the patient. Occasionally a patient who had been treated in this manner had subsequently consulted some local physician, who, finding a new and puzzling condition of things, applied some irritant resulting in injury, and the operation had been condemned unjustly. Dr. Sexton's experience had been that when patients had been told frankly before the operation what could be expected and what not, they had been satisfied and there had been very few disappointments. In young persons the amount of improvement in hearing had often been startling, while in older persons, those of forty or fifty years, it was naturally less. In purulent cases there was nearly always decided improvement in hearing. There was something in the technique of the operation, especially in sclerosis, for it had to be done with great delicacy. Subsequent reproduction of the drumhead might take place, but it could be easily removed again without pain if cocaine were used. He had observed cases in which the explosion of a shell had knocked a hole in the drum membrane, and although the membrane had not been reproduced the men had not suffered from deafness. Five or six soldiers in the ordnance department in whom he had noticed this (due to the explosion of a mortar shell at the United States Army proving grounds at Sandy Hook) did not complain of deafness when they were examined some time after the accident. In practice he was unable to explode a shell to make this opening, with but little local irritation, but he could do it with delicate instruments. An operation was the only treatment of much benefit to patients with sclerosing inflammation. Inflation, throat treatment, the use of pilocarpine, of electricity, of so-called massage, etc., were only a waste of time resulting in disappointment. Many of his patients had passed through all this at home and abroad and had received no benefit, and it was from operations on such unfavorable cases that many of his good results had been obtained.

Dr. ROBINSON remarked that there were prominent otologists who doubted the utility of this operation in sclerotic cases, and it was to this class that his remarks at the former meeting applied. On the other hand, he knew some very eminent specialists who favored it in suppurative cases. He would ask Dr. Sexton how he would account for the opposition in the dry cases.

DR. SEXTON would reply, without going tediously into the history of the matter, that such work was begun in a simple way half a century ago by Sir Astley Cooper, and twenty-five years ago the Germans resorted to it, for the most part on hospital patients, and as this class was usually the more unfavorable one they failed to establish reliable indications for the procedure in sclerosis. It was more difficult abroad to introduce radical innovations in practice, and aural surgery in this direction came to a standstill in many places, as in Berlin and in London. In the United States it was different, for Dr. Sexton had not found such reluctance on the part of patients in private practice to whom he had recommended it. It was not to be supposed that it was applicable in all cases of deafness. Probably he did not resort to it in catarrhal inflammation with one out of twenty sent to him especially for the operation. Nor did he believe the medical profession was as much divided with regard to it as Dr. Robinson seemed to believe. One reason perhaps why it was not more commonly practised was lack of time to become familiar with the details—the *modus operandi* of the operation. However, the literature of the subject for the past five or six years shows that much successful work has been done in Germany, France, England, Holland, Italy, Sweden, and the United States. Were not so many years usually spent by patients with advancing sclerosis in unavailing devices, very much more satisfactory results than any hitherto reported would be obtained.

Treatment of Fracture of the Patella by Continuous Extension without Confinement.—DR. JOSEPH D. BRYANT read the paper (see p. 472).

DR. GIENEY inquired what the results had been with regard to bony union or close fibrous union.

The Method is too Elaborate.—DR. ROBERT ABBE said the method appeared to him as too elaborate and as not consistent with the most recent views of the treatment of fracture of the patella. He thought the fixation method pure and simple gave practically perfect results. It consisted in putting a plaster casing over the entire limb, leaving a fenestra at the central part, applying figure 8 strips, and keeping the patient abed. Then came the suture method, which every one admitted gave the most perfect results, barring risks. But the risks were so great that even the most able men were afraid to use it in all cases.

Recently a method had come into vogue which seemed to him more reasonable than elaborate fixation with splints. He referred to massage while the patient was up and about, after ten days or two weeks. Championnière had recently written a book in which he advocated the principle and gave beautiful results from its practical application. When one remembered that there must be fibrous separation of the fragments in any form of fixation treatment except that of suture, it appealed to reason that the massage method might give as good results as any. A dog's broken leg formed a better callus while it was walking about than if the limb were put up in plaster of Paris. If in fracture of the patella the limb were fixed, the callus would separate or stretch half an inch or more a short time after beginning use of the limb, whereas the callus which formed under massage treatment was said to be a stronger one. The patient was kept abed about two weeks while effusion was subsiding, then with light support he was permitted to go about and massage was repeated every day rather vigorously. The muscular atrophy seen after the fixation methods was avoided. While he had not tried the method himself he felt much confidence in it.

DR. SEXTON remarked that some years ago he found a frog's leg at the dinner table which had been fractured and had healed by callus in remarkably natural position. There must have been much motion during

the healing process. He sent it to DR. GROSS, who expressed much interest in it.

DR. ROBINSON inquired whether Malgaigne hooks were any longer used for coaptation of fragments in fracture of the patella.

The president, DR. ANDREW H. SMITH, asked Dr. Abbe if anything was done to bring the fragments together, for otherwise it would seem they would be likely to remain widely separated. As far as his observation had extended, it seemed there had been a wonderful amount of uncertainty among surgeons in the treatment of fracture of the patella. About ten years ago he was compelled to attend a case in the country and several of the most eminent surgeons in the city were called in consultation. Perhaps the most eminent one had the whole anterior part of the thigh covered with adhesive plaster, a similar piece was put on the leg, and the two were drawn together by straps, with about as much influence on the fragments of the patella as if nothing had been done, for only the skin was pulled upon while the parts below retained their former position. This was in very hot weather; the patient endured the torture for three days and then the adhesive plaster was removed, exposing an excoriated surface underneath. Finally a figure 8 strap was applied and the patient recovered with good union, being able to dance and to use the limb subsequently as well as anybody. He thought there was much need of agreement upon some rational mode of treating these cases.

DR. ABBE replied that if the fragments were strongly disposed to separate, they should be approximated and held in position by pad and figure 8 straps until a callus was thrown out, and then massage would tend to fortify this.

DR. BRYANT said he had not intended to open up the general subject of treatment of fracture of the patella, for it was a pretty large one and, as others had remarked, it was far from being settled. There were some who believed in wiring the patella in every case of fracture, and while they had reported remarkable results, personally he was not one who believed the patella should be wired simply because it was broken. The method which he had described had nothing particularly novel, but commended itself because the patient could be up and about his room in about ten days.

It was Dr. Bryant's custom, when a case of fracture of the patella entered the hospital, to direct the house surgeon to apply an Esmarch bandage in order to reduce the swelling, and it was remarkable how small an amount of effusion was present after leaving the rubber bandage on for forty-eight hours. Dr. Abbe had spoken of fibrous tissue then preventing the fragments from being brought together, and although this was one obstacle Dr. Bryant had found firm blood clot a greater one, as proven in cases in which he had wired the patella. He had no reason to think that bony union between the fragments ever took place unless they were wired. Therefore he made no claim for the method described in his paper of securing bony union. He had never employed the massage method. Certainly the limb must be confined at some period, in order that the callus might have opportunity to harden. But the greater the movement the larger the callus, as was seen in fracture of the humerus, etc. He could commend the treatment described in his paper as one which would give as good results as any non-operative method and at the same time it would allow the patient to walk around. He mentioned the case of a man with fracture of the patella who refused to have it wired. It united with half an inch separation. Fracture occurred subsequently in the same line and he supposed that then he would surely have opportunity to wire the fragments, but the man again absolutely refused

to allow it. Union took place with three or four inches separation, and the man never met him in the street but what he danced a jig and reminded him that wiring was not a necessity.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 23, 1896.

E. D. FISHER, M.D., PRESIDENT, IN THE CHAIR.

Clubfoot and its Treatment.—DR. A. M. PHELPS read the first of three papers announced on clubfoot. The varieties of clubfoot were, he said: 1, congenital; 2, non-congenital; 3, paralytic; 4, non-paralytic. The paper had to do only with the congenital form, more particularly talipes equino-varus. Besides the more or less complete paralysis of one group of muscles, there was contraction, spastic or otherwise, of the opposing group, which caused deformity. Opinions differed regarding the cause of the congenital forms, but all, perhaps, admitted that heredity often played an important part. Where there was lack of amniotic fluid, intrauterine pressure might produce clubfoot; sometimes there was clubfoot on one side, bowleg on the other. Maternal impressions could be excluded. Specimens were shown of clubfoot at the second, fourth, and sixth months of intrauterine life, and up to the sixth year of age. It was apparent even at the earliest period that the astragalus was twisted inward. There was also contraction of the anterior division of the deltoid ligament, shortening of other soft structures on that side, later a wearing off of the articular facets of the astragalus, and more or less displacement of scaphoid and other bones.

The treatment of congenital clubfoot should be begun from birth. Manipulation practised daily up to the third month would remedy ninety per cent. of the cases. In some instances it might require five months, but usually he operated if a satisfactory result had not been obtained by the third month. Treatment should begin with subcutaneous tenotomy, straightening the foot and placing it in supercorrection. If one stopped short of that, there would be relapse. If subcutaneous tenotomy of opposing tendons did not permit of overcorrection, he divided the contracted skin and fascia, or whatever soft structures offered resistance. If overcorrection was still impossible, he did osteotomy. Finally, failing in all these, he performed Pyrogo's amputation of the foot. But osteotomy was seldom required. In young children the foot could best be retained in the corrected position after manipulation by passing adhesive plaster around the outer side of the foot up on the leg. It was superior to all apparatus.

Illustrative cases were shown. One was that of a girl, fourteen years old, with double equino-varus, who was taken to an orthopaedic surgeon when six months old, and treated for years by apparatus. Finally an insufficient tenotomy was done, which failed to fully correct the deformity. Dr. Phelps saw her last spring, divided the tendo Achillis, skin, abductor pollicis, plantar fascia, etc., and then made overcorrection. The feet now presented good shape. In this case and others in which apparatus had long been worn the pressure had caused the toes to permanently overlap.

DR. LEWIS A. SAYRE was unable to be present to read his paper on "Congenital Clubfoot and its Proper Treatment as Soon as Discovered." It will be published later.

The Place of Forcible Reposition in the Treatment of Clubfoot.—DR. REGINALD H. SAYRE said he had chosen this subject for his part of the discussion because he thought it had not received the atten-

tion which its importance demanded. He also began treatment by manual correction and did not resort to operative measures until this had failed. It appeared from the literature that many surgeons were prone to resort to extensive bone operations on feet which could be placed otherwise in more useful condition with less risk to the patient. Regarding overcorrection at one sitting, he thought he had sometimes obtained rather better results by going slower, making subcutaneous section where it seemed necessary and correcting the position as far as possible, and somewhat later further reducing the deformity without necessarily doing another operation. His ability to make further correction with less difficulty than at the time of the operation was explained on examining the distorted astragalus, for the articular facets were found to have become worn down, thus removing an obstacle to replacement. He was convinced that in many cases correction could thus be secured without a bone operation.

Dr. Sayre presented an instrument for forcible reposition of the foot, the use of which would often save an osteotomy. Subcutaneous tenotomy having been performed, the foot was fastened in a lever which was capable of exerting a great deal of power. The one devised by Dr. Phelps was best suited to talipes equinus; the other gave a better purchase in varus. After forcible reposition, plaster of Paris was applied. When the patient walked the weight of the body tended to force the foot into better position. He had observed a better result where reposition had been effected by tenotomy and this instrument than where osteotomy or removal of the astragalus had been resorted to. He did not mean to say, however, that osteotomy was never demanded.

The Influence of Experience on the Use of the Knife.—DR. W. R. TOWNSEND thought Dr. Phelps had omitted an important part of his paper, his statistics, that one might compare them with other methods of treatment. The principal thing was to correct the deformity. This could be done by different means. Failures were numerous, but the principal fault rested with the surgeon rather than with the method. The majority of men had not sufficient patience to carry on treatment every day for months or a year. How long mechanical treatment should be continued, whether three or twelve months, would depend on the case and on the orthopaedist. There could be no doubt of the value of operative treatment where for any reason mechanical treatment failed, but he thought the success of Dr. Phelps' procedure depended chiefly on the great force which he was able to apply in effecting reposition. The failure of others was in not making as complete correction or overcorrection. There was no doubt that the longer a man lived the less operating he did, and that he saw an increasing number of cases in which he could make reposition without resorting to the knife. It seemed to him that a foot which could be replaced by forcible measures was a better foot than one which had been operated upon.

DR. PHELPS showed his osteoclast, which was adapted to reduce any form of clubfoot. Regarding statistics, he said that in 1891 he had reported one hundred and sixty-one operations, eight of which were osteotomies, with no deaths and ten relapses. Since then he had operated without osteotomy about one hundred and eighty-one times, resorting to osteotomy but twice and to amputation once, with no deaths. In the hands of others osteotomy gave a mortality of from one and a half to five per cent. Had he resorted to osteotomy as often as was customary with many other surgeons he would have had, at their mortality rate, nine deaths instead of none. He therefore never did osteotomy except when necessary as a secondary operation.

A Synopsis of the Modern Treatment of Chronic Cardiac Disease.—DR. WILLIAM H. MCENROE read the paper (see p. 474).

Primary and Secondary Heart Disease.—DR. WILLIAM H. THOMSON said he would speak of only one or two points connected with the treatment of heart disease. In the first instance it was necessary to distinguish between cases of primary heart disease and cases secondary to disease in some other part of the body, as the kidneys. Primary heart disease was almost invariably from rheumatic poison, usually in early life. Chorea cases were no exception. But why should rheumatism, which left almost no traces in the joints the day after subsidence of the inflammation, prove so injurious to the endocardium? It was because the heart with its valves was in constant motion, having no opportunity for absolute rest such as was allowed the knee and other joints. This constant irritation led to changes which increased, as by a form of cicatricial contraction of the valves, and became permanent.

Rest and Aconite.—The indication was rest, and this was best secured by keeping the child abed and giving aconite. No greater mistake could be committed than to allow a child with rheumatic fever to get up too soon. In primary endocarditis, digitalis was not to be compared in value with aconite.

Totally different was secondary heart disease, which depended upon some obstruction to the circulation through the vessels. The enlargement of the heart in these cases was lateral and to the right, while in primary endocarditis in children it was upward and to the left of the sternum, and might even cause dullness up to the first intercostal space. First, there was in the secondary form hypertrophy of the cardiac muscles from overaction, but hypertrophied muscles were always shorter lived and one must watch for the first indications of dilatation. This was shown by increased frequency of the pulse. Our ideas of treatment of this class of cases had changed. We must increase the power of the heart muscle and let the valves go. The patient must take walks, even to the extent of six miles a day.

Mentioning pericarditis, nothing gave so much relief where the heart was bound through its envelopes to the thorax as strapping the latter firmly on that side by adhesive plaster. Where no such adhesions existed pericarditis frequently caused no symptoms.

Rest in Bed.—DR. WILLIAM H. DRAPER had learned to depreciate more and more cardiac drugs and to appreciate more and more the value of rest in cardiac disease. Certainly in the class of cases seen in hospitals one would be surprised to learn how much the improvement which took place was due to rest in bed. But rest was something which was usually prescribed in a perfunctory way. In reality it meant a great deal in these cases. It meant reduction of the heart beat fifteen or twenty a minute; it secured equilibrium of the circulation, etc. Next in importance came dietetic management. Many of the symptoms of valvular disease were aggravated or were due to gastric disturbance with fermentation, embarrassing the heart, lungs, etc., by pressure. Regarding drugs, he said that he had tried all the cardiac stimulants and had come to the conclusion that there was no one so universally useful as digitalis. It was commonly useful in affections of the mitral valve, especially those which increased frequency but diminished force of heart beat. It was not so useful in aortic regurgitation until this had become complicated by mitral insufficiency.

DR. MCENROE made a few remarks in closing.

The special committee, through DR. GRANDIN, reported resolutions on the death of Dr. Alexander S. Hunter, which were unanimously adopted.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, March 26, 1896.

W. R. PRYOR, M.D., CHAIRMAN.

Difficult Delivery.—DR. A. ERNEST GALLANT related a case of difficult delivery due to excess of adipose tissue in the mother's pelvis and to great circumference of the infant's shoulders. The woman weighed two hundred and twenty pounds, the child's head was of ordinary size, but the circumference at the shoulders was unusually great, interfering with completion of delivery after the head had been safely, although with difficulty, extracted by forceps. The excessive compression of the child's body due to the combined conditions, great circumference at the shoulders and adipose tissue narrowing the mother's vagina, caused its death. The case was also of interest from the fact that no hernia had developed, although a scar existed where some months previously he had performed an operation for appendicitis. Only a single line of sutures had been used.

Blighted Twin.—DR. PHILANDER A. HARRIS presented twin fetuses, one of which was apparently of about the seventh month and measured thirty-three centimetres; the other one was blighted, body and head being quite thin and flattened, and the length nineteen centimetres. The larger of the two seemed to have been in excellent condition until about the time of birth. The patient had been attended by another physician. She had four other healthy children, the oldest two being twins.

Ovarian Tumor with Twisted Pedicle; Hæmatoma.—DR. HARRIS also presented an ovarian tumor larger than an orange, with a narrow pedicle which had permitted the tumor to become twisted around it twice. At the time of operating he also found a hæmatocele at the right of the tumor which had been the cause of some difficulty in diagnosis, for by its presence it had forced the tumor, which formerly had been felt on the right side, over to the left side of the abdomen. The hæmatocele had arisen from rupture of a vein at the time the tumor had become twisted on its pedicle.

Dumbbell Fibroid of Uterus.—DR. HARRIS also showed a uterus with so-called dumbbell fibroid, or double fibroid, springing from its two sides. He had chosen to remove the uterus with the tumors because the woman had had no children, although married sixteen years.

Retroperitoneal Abscess Following the Puerperium.—DR. E. E. TULL presented an unbroken pus sac about the size of a hen's egg removed two days before from below the peritoneum, it having been attached to the omentum in the right iliac fossa. The patient, who had been confined by a midwife, came to the clinic with a temperature of 105° F. The uterus had already undergone involution and was found at the operation, together with ovaries and tubes, to be practically normal. The sepsis, therefore, seemed to have taken place without involving the tubes and ovaries. He had seen two other similar cases of abscess which had formed during the puerperium independently of the tubes and ovaries. In one the abscess was high above the uterus in the folds of the omentum; the pus poured out and infected the peritoneal cavity, causing death.

Carcinoma of Cervix; Multilocular Cyst of Ovary.—DR. H. N. VINEBERG presented what he said was a rather rare combination of specimens from the same patient—large cancer limited to the cervix uteri and multilocular ovarian non-malignant cyst. The woman had had no signs of cachexia. The operation, an abdominal hysterectomy, was difficult, there

was considerable hemorrhage, and fully two feet of the intestine was laid bare of omentum.

Spoon Depression of Fœtal Skull.—DR. SIMON MARX said the specimen which he was about to present was somewhat rare in this country, although common enough in Germany. It was a part of the fœtal skull, including one parietal bone, showing so-called spoon depression which had occurred during labor. The woman had been in labor twelve or fourteen hours before he saw her. The head was above the brim and the os fully dilated; the pelvis was small and flat, its true conjugate being 3.75 inches. He performed version and without trouble extracted the baby. The heart was beating slowly, forty a minute, but the child could not be revived. The depression was in the left parietal bone, which had rested on the brim of the pelvis, and beneath was some old blood.

Discussion on the cases being in order, Dr. Marx said concerning Dr. Tull's that in one instance two surgeons had made a diagnosis of appendicitis, but operation revealed retro-peritoneal abscess.

DR. VINEBERG was disposed to think from some observations and studies which he had been making that these abscesses were due to small hæmatomata occurring during labor. He believed that such hæmatomata occurred oftener than stated in statistics, once in 1,500 or 3,000 cases of confinement, and while some of them became absorbed, others suppurated and formed abscesses, which might be subperitoneal, extraperitoneal, or involve other tissues.

DR. R. W. MURRAY thought that when a septic condition was met with during the puerperal state one should make examination by rectum before operating. In this way many obscure cases could be made clear.

DR. MALCOLM McLEAN remarked that the inference was not to be drawn from Dr. Harris' case that where one fœtus of twins became atrophied and compressed it was likely to cause death of the other. As a rule the healthy fœtus remained healthy, went on to develop, and was born normally at term.

DR. GALLANT, referring to Dr. Vineberg's specimens, said that advanced carcinoma of the cervix or of other pelvic tissues without general cachexia was frequently seen at the Cancer Hospital.

DR. E. A. TUCKER said he had seen three or four cases of so-called spoon depression of the fœtal skull and all the children lived.

Alexander's Operation and Hernia.—The Chairman, DR. PRYOR, asked for statistics bearing on hernia following Alexander's operation. At a recent meeting Dr. Ill, of Newark, had stated that he had seen fourteen cases of hernia after this method of lifting the uterus, and had confirmed his statement by letter in answer to one from Dr. Pryor. Another gentleman had told him he had seen nine cases, and to these he could add three more, making a total of twenty-six.

DR. JOSEPH BRETTAUER, the gentleman who had seen the nine cases, stated that he was himself a believer in the Alexander operation under proper conditions and when carried out, as it could be, without suppuration and with primary union. He knew of no reason why hernia should occur under such circumstances, but believed that it was due to suppuration.

THE CHAIRMAN mentioned the fact that there were two methods of performing the operation, one consisting in opening the canal, the other in making an incision at the insertion of the ligaments at the spine of the pubes and searching for them there, without entering the canal at all. It would be interesting to know what proportion of the cases of hernia had occurred in each class.

Three Warnings of Interest to Obstetricians.—

DR. J. MILTON MABBOTT read the paper. The warnings referred to were for obstetricians to convey to mothers. They were extremely simple in character,

yet they were important to life. 1. Warn women not to neglect any kind of hemorrhage during pregnancy. Dr. Mabbott had seen two cases of death due to hemorrhage which might have been prevented had the patients notified the physician earlier. 2. Warn women during confinement to keep the hands away from the vulva and vagina. It was difficult to say how many cases of infection had arisen from neglect of this precaution, but he knew of one case of fatal pyæmia in a colored woman which could be accounted for in no other way than by the fact that she had examined herself after delivery to learn in what way the genitals differed from their previous state. 3. Warn nursing women never to fall asleep with the infant at the breast. It was not sufficient simply to have the baby sleep in a separate bed. The writer had had two cases of death of the infant from suffocation by falling between the mother's breasts while she was asleep. A separate bed would prevent overlying, but it would not prevent this accident.

DR. E. A. TUCKER thought the three warnings were important, but he was not sure that they would be observed if given. Carelessness was at the bottom of the trouble. With regard to hemorrhage, it would seem that intuition would tell the pregnant woman of its danger and lead her to consult a physician, yet that this was not so was illustrated by the case of a woman who had been a nurse before her marriage and died of recurrent hemorrhage due to placenta prævia, because of failure to consult a physician early. To prevent overlying, the child should sleep in a separate bed. It had been argued that it would thrive better if it were warmed by the animal heat of the mother, but Dr. Tucker doubted this.

DR. E. E. TULL thought the child should not nurse longer than ten minutes. This limit of time would render suffocation from falling between the mother's breasts less liable to occur and would also tend to prevent sore nipple.

Beer and Overlying.—DR. L. F. BISHOP said this subject was discussed very often in foreign periodicals, but had not been much agitated in this country, yet the accident was not infrequent. In London a thousand healthy children lost their lives in this manner every year. He had once been called to a case in which the mother and father had been drinking beer on Saturday night, and on retiring they had put the child between them. Next morning it was found dead. Only a little liquor was sufficient to prevent the natural reflex movements during sleep which would warn the mother of lying on her child. It was important to know that the face of the child was not necessarily livid and swollen, but often presented a natural appearance after overlying. Our conclusion as to the cause of death must often rest to a great extent on the history of the occurrence. Dr. Bishop also related a case showing carelessness on the part of the mother about consulting the physician for hemorrhage, which in this instance was due to retention of a dead fœtus.

Three Warnings and Many Others.—DR. P. A. HARRIS remarked that there were these three warnings and many others, and the only question was whether they would be followed if given. Regarding danger of infection from the mother's hands, he thought a similar warning might well be given midwives. He recalled a paper on the habit of negro midwives in a Southern city. It was stated that they never made a vaginal examination, and although the surroundings of these people were very filthy, puerperal fever was very rare.

DR. BROOKS H. WELLS said the remark made by the last speaker applied equally to certain Indian squaws: they never allowed the finger to go near the vagina or vulva during labor, and they were wonderfully exempt from puerperal fever.

Intentional Overlying.—DR. MARX said that in institutions young unmarried mothers were sometimes guilty of deliberate overlying, for in their condition they stood little chance in a great city. One source of infection among the ignorant classes was early approach of the husband after labor.

THE CHAIRMAN stated that it was undoubtedly true that many puerperal women were in the habit of examining themselves to see how they were getting along. The custom mentioned as presumably peculiar to negroes in the South existed also to some extent among women of the highest classes, who preferred to be attended by a midwife who made no examinations than by a physician, however skilled he might be, who was in the habit of making repeated examinations. Pure-blooded negroes were said to be less susceptible to inflammation than white people, which might in part account for their freedom from puerperal fever.

DR. MABBOTT thought that those who should neglect to give these warnings because of belief that through carelessness the women would not heed them, themselves showed a careless mind which ought first to be corrected. Regarding midwives, he would, as stated in a former paper, have them act the part only of nurse, and allow nobody to make a vaginal examination except a physician.

Clinical Department.

SKIN-GRAFTING AND CORN-HUSK PROTECTIVE DRESSING.

By FRANK OVERTON, M.D.,

PATCHOGUE, N. Y.,
LATE HOUSE SURGEON AT CITY HOSPITAL, NEW YORK.

THE following case gives a good comparison between Reverdin's method of skin-grafting and the method of grafting from a blister as described by Dr. Lusk in the MEDICAL RECORD, December 7, 1895.

The patient was a very nervous girl, seventeen years of age. Just above the left angle of the jaw there was an ulcer two inches in diameter, the result of curetting a suppurating wen on January 3, 1896. On January 10th the granulations looked perfectly healthy. A cantharides blister was applied to her arm, and two pieces of the raised epithelium, each of the size of the thumb nail, were cut off and applied to the anterior part of the wound. The Lister protective being damaged, an iodoform gauze dressing was applied directly to the wound. On the 16th this was removed and with it one of the grafts. Another area the size of the first was blistered and the epidermis applied just posterior to the first grafts. In place of the Lister protective, thin corn husks were used to cover the grafts, and an iodoform gauze dressing was applied as usual. On the 24th the area of the first graft seemed to be covered with epithelium, but the cells were too thin and too transparent for me to be sure of their presence. The posterior area seemed slightly shiny in appearance, but it was doubtful if it was due to live epithelium. On the same day the lower posterior part of the wound was grafted according to Reverdin's method with four or five pieces of skin taken from the mother.

On January 29th both areas of the blister grafts looked healthy, but three of the grafts taken from the mother looked as healthy and vigorous as those from the blister, although the latter had been growing three times as long as the former.

On February 1st all the areas of grafting looked healthy and had nearly covered the ulcer, but those from the mother were growing far more rapidly than

those from the blister. The conditions were the same for all the grafts. They were applied directly to the granulations and there was no curettage or other preparation of the ulcer. Judging from this one case, grafts raised by a cantharides blister will grow, but they have poor vitality as compared with grafts cut from normal skin.

Very thin corn husks were selected to be used in place of the Lister protective. They were sterilized in 1 to 40 carbolic acid. Just before using they were washed in plain sterilized water and oiled with sterilized oil. They proved satisfactory in every way. They did not adhere to the granulations, as it was feared they would from their porous character. Their strength is amply sufficient to stand as rough usage as the wound is likely to be subjected to by the dressing. They have the great advantage that if they do adhere they can be removed by tearing off successive strips as narrow as one-sixteenth inch each. A narrow strip can be torn down the middle of a piece of dressing in order to examine the parts beneath without disturbing the whole dressing.

MARGINAL PLACENTA PRÆVIA—ANTEPARTUM HEMORRHAGE, WHICH DIMINISHED IN INTENSITY AS PREGNANCY ADVANCED—FATTY DEGENERATION OF DEPENDENT PART OF PLACENTA—SPONTANEOUS DELIVERY PREMATURE—SHOULDER PRESENTATION.

By J. F. SHELLEY, M.D.,

ELMDALE, KAN.

PATIENT aged thirty-eight, well built and well nourished, called at my office February 18, 1895, to consult me about hemorrhages from the uterus. She stated she had menstruated regularly until September, 1894, when she menstruated the last time until the latter part of January, 1895. She described a sudden hemorrhage at this time more profuse than menstrual flow but lasting for only a short time.

Family history as to any specific or tuberculous trouble was entirely negative, but there was some tendency to rheumatism in family, otherwise nothing of note. Previous history, always in fairly good health. Had had six children, all natural birth except at the third delivery when there was shoulder presentation.

The hemorrhage of the end of January was repeated about the middle of February with the same characteristics, only the flow was more profuse, and the repetition of these singular phenomena brought her to me for advice.

Examination revealed nothing out of the ordinary condition of the pregnant uterus at this stage, and the pelvis was roomy and seemingly had no irregularities. Patient was feeling well at time of examination.

A diagnosis of probable placenta prævia was made and instructions were given for procedure in case of subsequent hemorrhages, and frequent reports were requested. These reports were made at irregular intervals and they were to the effect that the hemorrhages were rapidly diminishing in frequency and intensity. On April 27th they brought me some masses of tissue which had undergone fatty degeneration. Such matter, they explained, had frequently been expelled from the uterus for some six weeks immediately preceding this time. At times, in fact generally, the expulsion was accompanied with some bearing down and pain. The largest mass they brought me weighed about ten grams. The expulsion of the matter was also sometimes accompanied by slight loss of blood.

May 11th, I was called to find the woman in labor.

The os uteri on my arrival was dilated sufficiently to admit two fingers. The membranes could be felt intact, but a mass of detritus with a semi-granular feel, having no special odor, could also be detected. Part of this lay loose in the lower section of the uterus, but could be felt in mass to the left of the median line. The first thought was that I had septic decomposition of some structure, and yet movement of the fœtus made life certain, though I could elicit no fœtal heart sound. The granular mass to the left was unlike the placenta, but with previous history and present condition in view I concluded it must be that body, and in fear of hemorrhage I watched the case closely while I sent for an assistant in the person of Dr. Johnson. To my satisfaction hemorrhage did not appear. As the os dilated the child was felt high up in the uterus, and when examination, which was very painful, could be sufficiently made it revealed a shoulder presentation.

Dr. Johnson having arrived, it was determined to anæsthetize and deliver. Membranes were ruptured, podalic version affected, and a two and one-half pound babe delivered, asphyxiated but later resuscitated. Hemorrhage was not sufficient to attract especial attention. The placenta was delivered and showed circumscribed fatty degeneration of one side.

The uterus was not irrigated after delivery, and yet no rise of temperature above normal occurred at any time after delivery. The mother made speedy recovery and the child did well from the start.

The case is of special interest in again illustrating the tendency of placenta prævia to cause shoulder or transverse presentations, and in the means seemingly used by nature against hemorrhage and obstructed labor from placenta prævia. The fatty degeneration was probably instrumental in producing premature labor by presenting a foreign body to cause irritation of the os uteri, and the wonder would seem to be that it had not produced it sooner.

ABSCCESS OF THE LUNG TREATED BY INCISION AND DRAINAGE.

By G. K. SIMS, M.D.,

DEPARTMENT OF SURGERY AND GENITO-URINARY DISEASES, FREE DISPENSARY,
UNIVERSITY COLLEGE OF MEDICINE, RICHMOND, VA.

ABOUT the middle of October, 1895, L. L.—, aged twenty-five, received a pistol wound of the chest on the right side between the second and third ribs, in the axillary line. It bled freely externally and there was some expectoration of blood. The wound was cleansed and dressed antiseptically, and a hypodermic injection of morphine and atropine was given. The expectoration of blood-stained mucus continued for about a week, followed by a cough and temperature of 101° to 102° F. for two weeks longer, then gradually declined. The external wound healed and he seemed nearly well, when the temperature began to rise again with symptoms of secondary pneumonia. In the course of about two weeks he began to have severe sweats and other symptoms of pyæmic intoxication. Later on the subcutaneous tissues over that whole side became very œdematous and physical signs showed consolidation of the whole right lung. Repeated aspirations failed to get any pus, but as he was rapidly growing worse it was decided to make an incision and find the abscess. This incision was made between the third and fourth ribs, and soon after piercing the pleura there was a gush of very offensive pus, about two quarts being discharged. The cavity was washed out with sterilized water, a drainage tube was inserted, and the wound was dressed with iodoform gauze and absorbent cotton. Though very weak, the patient rallied from the operation very well and began to

improve: the fever, cough, and sweats declined and the appetite returned. The cavity was washed out daily with a 1 to 5,000 bichloride solution followed by sterilized water. The cavity gradually became smaller and the pus diminished until now there is a very small cavity and he is nearly well. Some peculiar points in this case are the long time before abscess formation, the absence of rigors, profuse sweats, the pitting œdema of the side, and intense nausea and vomiting. The medical treatment was mainly symptomatic and sustaining—iron, quinine, strychnine, whiskey, and concentrated liquid food—buttermilk being the only thing he could relish.

Surgery of the lungs is yet to be developed. Possibly the cure of pulmonary tuberculosis will be achieved in this direction in the near future, unless some more potent medical remedy is found.

621 EAST FRANKLIN STREET.

FATALITY OF MEASLES POSSIBLY DUE TO DIPHTHERIA.

By CARL D. S. FRÜH, M.D.,

PHILADELPHIA.

THE writer was consulted by the mother of a boy five years of age for a remedy to ease a persistent cough of some days' standing. She described it as a barking cough.

The following day, being called to see the child, I found it had a typical attack of measles, some swelling of the glands of the neck, a fever of 101° F., and the peculiar cough described by the mother.

The throat was reddened but no patches indicating diphtheritic membrane were observable, nor was there any offensive odor of the breath. As the fever continued for several days after the eruption, a culture was made and referred to the bacteriological department of the Philadelphia Board of Health.

His case proved to be one of true diphtheria.

Antitoxin was injected into the buttocks (after freezing with chloride of ethyl) at intervals of twelve hours. Before the second injection was introduced a marked change had taken place in the child, the cough having decidedly lessened in intensity and the temperature becoming normal.

This case has impressed me greatly as one of many that possibly occur during the prevalence of measles and diphtheria.

IMPERSONATION OF A WOMAN.

By V. S. BIRD, M.D.,

TAMPA, FLA.

THE following are the details of the most remarkable instance of passive pederasty of which I have any knowledge.

For nine years before his death an individual known as "Big Six" was notoriously prominent in this part of the State as a prostitute. During a part of 1894 he lived in this town. His nickname was suggested by his unusual size and strength, especially as he was supposed to be a woman. During these nine years his sex was never suspected. He would never submit to an examination. There is in this town a man who was formally married to him, living with him as man with wife for six months. I understand from an intimate acquaintance of this man that he says positively that "Big Six" was a woman.

After a short illness it was remarked that his beard was noticeable for a woman, but no deduction was drawn from it.

In regard to the illness preceding his death, which occurred about December 20, 1894, I can learn but

little. Dr. J. F. Cronin with another physician visited him during the day before his death, and has kindly given me the following facts:

At the time of their visit he was unconscious and apparently moribund. While the physicians were in the room several fecal discharges occurred, the odor of which was so disagreeable that they retired as soon as possible. He was much emaciated and was said to have had a diarrhoea during a month or more before his death. Two days before his death his sex was discovered. Dr. Cronin examined him, and says that the penis, testicles, and scrotum were well developed. He mentions no anomaly, which he undoubtedly would have done if any had been noticed. I have no record of an autopsy. The remains of a rubber appliance were found in his room, which is supposed to have been used by him while personating a prostitute.

The case is interesting to me because it is the only one of the kind I know of.

THE ANTISEPTIC VAGINAL DOUCHE AFTER DELIVERY.

By W. E. McCONVILLE, M.D.,

DEMONSTRATOR OF ANATOMY, UNIVERSITY OF VIRGINIA.

The antiseptic vaginal douche after delivery has important physiological actions and is as necessary as many other duties performed by the accoucheur. It is often omitted through preference, as there are those who claim it is unnecessary and some go so far as to say it is harmful.

It seems, however, that with our present knowledge of the condition of the blood and tissues during pregnancy and their condition after delivery, combined with our knowledge of pathological processes, septic infection and its prevention, it is necessary for the safety and comfort of the patient regardless of how carefully the attendants and patient are cleansed before and during labor, for it is well known how easily a little septic material can gain access to the genitals and under favorable conditions cause serious and perhaps fatal trouble. It has been shown that the vaginal and cervical secretions are normally antagonistic to the growth of pathological germs, but after delivery the tissues generally have their powers of resistance diminished.

The condition of the tissues during pregnancy is too well known to require discussion, and it is only necessary to state that it is one of great hypertrophy. The blood shows a relative decrease in corpuscular elements with a corresponding relative increase in fluids and fibrin factors; thus the powers of resistance of both blood and tissues to infection are lessened.

After delivery the tissues naturally endeavor to resume their normal condition and to accomplish this undergo rapid oxidation, the products of which must be eliminated. To accomplish this open the veins and remove these products as rapidly as possible, but if the coagula and other debris are left to be even partially disposed of by the overtaxed tissues and vascular system, even if they be aseptic, their absorption would increase fibrin factors and might give rise to fermentation fever or thrombosis and embolism. The debris also offers suitable conditions for the location and propagation of pathogenic bacteria.

The douche removes the effete products, thus lessening the work of the impoverished blood, and it also destroys any bacteria that may have previously been present or have been accidentally introduced into the vagina during labor, thus directly lessening in two ways the chances of infection. If used sufficiently hot, as it should be, it also stimulates the blood-vessels and uterus to contract, in this way indirectly lessening

the danger of infection, the number and severity of the after-pains, and the chances of secondary postpartum hemorrhage. The heat also acts as a sedative on the peripheral nerve terminals and by its local and reflex action it produces a sense of comfort, and the patient will often drop to sleep and obtain a much-needed rest.

To summarize, then, the benefits of a douche are a rapid and pleasant convalescence and, as nearly as can be obtained in obstetrical practice, the conditions necessary for the primary repair of the tissues, which are a sepsis, hæmostasis, and rest.

A LARGE DOSE OF MORPHINE NOT FOLLOWED BY SYMPTOMS OF POISONING.

By HERMANN BOEKER, M.D.,

NEW YORK.

Miss D—, nineteen years of age, Irish, presented herself at my office in the evening of February 11, 1896, for treatment, showing the well-pronounced symptoms of acute catarrhal jaundice. I ordered rest in bed, a regulated diet, one dozen quarter-grain calomel tablet triturations, vichy water, and a compound rhubarb, soda, gentian, and nux-vomica mixture.

According to my directions she was to take three tablets immediately after receiving them from the drug store and one every hour following until the bowels had moved, after which she was to take the rhubarb-and-soda mixture in one-half tablespoonful doses. The next morning at 9 A.M. the druggist who dispensed the tablets and medicine rushed into my office and informed me that he had discovered that he had given quarter-grain morphine tablets instead of quarter-grain calomel tablets. I hurried to the patient's home and was somewhat surprised to see her opening the door. Upon inquiry she told me that she had taken seven of those tablets according to my ordination, but that "they had not moved her a bit." She had been quite restless all night and had imbibed almost the entire contents of one siphon of vichy water. I emptied her stomach at once by an emetic, by which she lost about one and a half pints of an almost clear alkaline fluid, and then administered a few ounces of a permanganate-of-potash solution, which was also vomited again after a few minutes, perfectly decolorized.

As the patient did not show the slightest effect from the drug, after a while I made her take real calomel tablets in quarter-grain doses, hoping to start the secretions and peristalsis of the intestinal tract, as I had intended originally. After seven hours, however, the calomel did not show the slightest effect and so I ordered a rectal injection of soapsuds and turpentine, with the desired result. The girl passed a large chamberful of feces, the latter one-third of which had the clay-colored appearance of jaundiced patients. After she had taken a few more calomel tablets, I put the patient on the above-mentioned mixture of soda, rhubarb, gentian, nux vomica, etc., under the influence of which she felt quite comfortable.

During my call at her house the next morning she assured me that "she never felt better in her life" and her appearance seemed to corroborate her statement, although the integument and conjunctivæ were jaundiced. She had not the remotest idea of the danger in which she had been, as I had told her that her druggist had given her tablets which had just the opposite effect from the one I desired and that for this reason I desired her to take the emetic.

In order to make sure that the tablets in question were really quarter-grain morphine tablets, I took the remaining five back to the druggist, a man of intelligence and conscientiousness, who convinced himself

soon by his taste and some chemical reactions that his mistake might have easily proven fatal.

The fortunate course of this accident, however, seems to indicate again that in acute catarrhal jaundice the secretions of the glands along the alimentary tract are almost at a standstill, that the ability of absorption through the stomach is greatly impaired, especially in the presence of a larger amount of an alkaline fluid.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE LECTURE SEASON—LETTSONIAN, MILROY, GOULSTONIAN, CROONIAN LECTURES—MEDICO-CHIRURGICAL SOCIETY—DINNER OF THE MEDICAL SOCIETY—FOTHERGILLIAN PRIZE—TUBERCULOSIS REPORT—SIR R. REYNOLDS—THE LATE T. W. THOMPSON.

LONDON, March 13, 1896.

WE are in the midst of the lecture season. Mr. Cheyne has given the Lettsomian lectures before the Medical Society, which he devoted to the "Objects and Limits of Operations for Cancer." Where operation is in his view advisable, he holds that it should be extensive; if possible he would remove all diseased tissue. On the other hand when it is impossible to eradicate the disease, and in cases when early return is almost certain and experience shows that the patient would be no better off than if left to the ordinary course of the disease, he is disposed so to leave him and not expose him to the additional risk of operation.

The Milroy lectures at the College of Physicians have also been delivered. Dr. Seaton was the lecturer this year and his subject "The Value of Isolation and its Difficulties." He treated it with the hand of a master, sketching the beginnings of isolation in this country from a modern point of view and then passing on to the problems of the present moment. He dwelt at great length on small-pox, much greater than it deserved if we look only at its death rate compared with those of other zymotic diseases, but none too great regarded from the point of its importance as a proof of the value of such preventive measures as are at the present day practicable. This was insisted on as the point of view for our sanitary administration. Still the lecturer suggested that the behavior of variola under different conditions which have been closely studied may not only throw light on epidemiological questions but enable us to extend preventive treatment to other diseases.

The Goulstonian lectures are not yet concluded. They were entrusted to Dr. Patrick Manson, who is devoting them to the malaria germ, respecting which his authority is well known.

The Croonian lecture of the Royal Society was delivered on Thursday by Dr. Waller, lecturer on physiology at St. Mary's Hospital, who devoted it to observations on isolated nerve. He described the method of testing the effects of substances of various kinds on nerve and then turned to anaesthetics. He found carbon dioxide more anaesthetic and less toxic to isolated nerve than either ether or chloroform, which last was the most toxic of the three. Ether was more anaesthetic than toxic, while chloroform was just the reverse.

The new president of the Royal Medico-Chirurgical Society, Dr. W. H. Dickinson, began his work on Tuesday with a suitable acknowledgment of the honor conferred upon him and an assurance that he would grudge no time or labor in promoting the welfare of the society. He gave no formal address,

but made the suggestion that the society should put itself into the position of a sort of court of appeal on medical science. Good work had been done by the committees appointed from time to time and he thought that it would be well if such committees were permanent, though of course the members might change.

The society then settled down to ordinary business. Mr. Mayo Robson read a paper on excision of a portion of the liver for tumor of the gall bladder. The tumor was removed with a portion of the liver. The patient is now quite well.

Mr. Ballance related a case of cyst of the brain, which was evacuated. Subsequently a tumor was removed weighing three ounces, and the patient left the hospital apparently well, but was readmitted three months later moribund. On post-mortem examination an enormous tumor was found in the left hemisphere.

The annual dinner of the Medical Society took place on Saturday. The president, Sir Crichton Browne, was in the chair and in an eloquent speech dwelt on the work of Prof. Victor Horsley on the thyroid gland, and then presented that gentleman with the Fothergillian medal of the society. In his reply Mr. Horsley said he had only completed the investigations of Schiff, Ord, Gall, and Murray by supplying experimental proof of the truth of their clinical deductions.

On Monday at the ordinary meeting of the same society Mr. Horsley gave a lecture on the "Physiology and Pathology of the Thyroid Gland," in which he gave a concise account of our knowledge of the subject from the time when Schiff first directed attention to the importance of the gland down to the present day. The lecture, which was illustrated by photographs on the screen, was listened to with great attention and a hearty vote of thanks was accorded to Mr. Horsley.

The report of the royal commission on tuberculosis forms a heavy blue book, but one that will doubtless play an important part. Witnesses were called whose experience gives special value to their opinions and the researches carried out by the assistant commissioners go far to settle certain important questions. It is obvious that our food supply is a source of great danger and that legislation is urgently called for to prevent the sale of tuberculous meat and milk, the more so as the sterilization of meat or milk in the process of cooking is shown to be unreliable. The danger of smearing the surface of joints by the butcher's knife or hands with bacilli from another part of the carcase is an ever present one: the presence of tuberculous glands in some joints is another source of infection. Considering these points, the fact brought out by the experimental inquiry that the bacilli, though destroyed on the surface of the joint by cooking, may resist the heat in the interior is of the highest importance. Nothing short of a vigorous attempt to stamp out tuberculous cattle seems to promise safety, and as the breeders and dealers cannot bear the whole loss that would be incurred, some scheme of compensation is called for. If the people once realize the danger to which they are exposed, they will scarcely grudge the expense of reducing the risk to a minimum and possibly removing it altogether.

The presidency of the Royal College of Physicians will be vacant on the 30th inst. and Sir Russell Reynolds declines to be re-elected. He has given great satisfaction and many would have liked to see him accept a second term. But he is well entitled to some repose.

The funeral of Mr. Thomas William Thompson, one of the inspectors of the Local Government Board,

took place on Saturday last and was attended by colleagues and sympathetic friends. He died on the 25th ult. quite unexpectedly, while engaged in Wales on an important sanitary survey. Mr. Thompson's intellect was of a very high order and the sanitary service of the country has lost in him one of its most able members. His reports to the Local Government Board reached the highest standard of the medical department, which has always availed itself of the best scientific work. He wrote the article on the "Natural History of Infectious Diseases" in Stevenson and Murphy's "encyclopedia" work on hygiene, and that is a piece of work of which any one might be proud. Mr. Thompson's experience was exceptionally wide before he entered the service of the Local Government Board. He had been a general practitioner and had previously had the training of both civil and military hospitals. Afterward he became medical officer of health for the Middlesex and Hertfordshire combined districts, and it was probably his excellent work in this capacity that attracted the attention of the central board and so secured his services for the country in the wider sphere. He seems to have been highly esteemed and even loved in all the positions he filled in his useful and full, if too short, life. He was only forty-four years of age at his death.

OUR PARIS LETTER.

(From our Special Correspondent.)

PHOTOGRAPHY OF A FETUS IN UTERO BY THE "X" RAYS OF ROENTGEN—INTERESTING MEETING OF THE ACADEMY OF MEDICINE.

PARIS, March 15, 1896.

The Rays of Roentgen.—The rays of Roentgen have made such a stir in the world that an illustrated newspaper is representing a husband conducting his wife to the doctor in order to have the sex of the expected child determined by means of photography through the abdominal walls. The author of this intended absurd joke little dreamed that there was some foundation of truth in it after all, as we shall now see.

The last meeting of the Academy of Medicine, held on the 10th inst., was particularly interesting, the more so as this very question of intrauterine photography was discussed. Professor Pinard, the eminent director of the lying-in hospital Baudeloque, read a communication in the names of his associates Varnier and Chappuis, from which it results that it is possible to photograph by the "X" rays a fetus in a uterus which has been kept for a long time in alcohol.

The piece used in the experiment was a gravid uterus of three and one-half months, extirpated in 1894 from the cadaver of a woman who had died of pernicious anæmia. It measured six centimetres, about two and one-quarter inches, in its greatest general thickness, which the "X" rays traversed. The photograph presented four capital points: 1, the silhouette of the body of the uterus with its annexes; 2, the muscular wall; 3, light, in the dark frame, the uterine cavity; 4th, the silhouette of the fetus glued to the uterine wall in the superior right-hand portion of the cavity.

It should not be forgotten, moreover, that the "X" rays went through not only the double uterine walls of a gravid uterus hardened by alcohol, but also through the bladder, placenta, rectum, etc.

There is, then, reason to hope that the uterine cavity, fresh and still full of blood, may be as easily traversed as the uterine walls hardened and densified by alcohol, and that the "X" rays may eventually realize all that is demanded of them by medicine, surgery, and obstetrics alike.

Appendicitis, a Designation to Embrace all Affections of a Typhlitic or Perityphlitic Nature.—Pro-

fessor Dieulafoy at the same meeting presented a paper demonstrating that the pathological notion of typhlitis and perityphlitis ought to be replaced by that of appendicitis, which should enter into medical nomenclature as an unique expression for all affections of the ileo-cæcal region and of typhlitic nature. There exist at times lesions of the cæcum—for instance, a tuberculous ulceration or an ulceration of other origin—but nothing can supersede pathologically the established fact that stercoral typhlitis is appendicitis and appendicitis alone is the cause. The pathogeny of appendicitis is identical with that of peritonitis consecutive to ligation of a loop of intestine, and, as Klecki has shown, due to the virulence of the microbes contained in the normal intestine, and which becomes much intensified in the loop or fold obliterated. It must then be admitted that in all cases of appendicitis there is obliteration of the appendicular canal. The professor, in closing his paper, insisted upon the necessity of substituting in the future for medical treatment surgical intervention as early as possible.

Professional Contagion of Cancer.—M. Guérmonprez called the attention of the academy to two cases that seemed to prove the possibility of the transmission of cancer by hetero-inoculation. The first was that of a physician who had a small wart in the temporal region. In consequence of scratchings on and about the wart, it began to ulcerate and became cancerous, as was demonstrated by histological examination. It is quite reasonable to suppose, in this case, that the physician, who frequently operated upon cancerous cases and who was himself entirely free from any hereditary taint, inoculated himself with the cancerous germs. The second case was personal to the speaker. After a slight subungual trauma in the course of an operation for cancer of the tongue, M. Guérmonprez had a small papilloma, which was destroyed by caustics. Although no histological examination was made, it was probably of cancerous nature.

The Prophylaxis of Malaria.—According to Professor Laborde the preventive action of quinine can no longer be doubted, as can be that of other similar substances, vegetable or mineral, such as curare, strychnine, arsenic, etc. He adds that if the preventive action of quinine has been contested by some authors, it is because that substance had been administered in too small doses (five grains generally) or too far apart, and insists upon advantages offered by the muriate of quinine in preference to the sulphate usually employed. It should be borne in mind that the word dose in France refers to the quantity given in twenty-four hours or to the whole quantity given to attain any special therapeutic result. The military statistics have proven effectually that quinine, even if given daily in small doses, is powerless to prevent an access of malarial fever. Even the employment of quinine at proper times and in doses sufficiently high gives but a deceptive security to doctor and patient alike, if other prophylactic and hygienic precautions are not observed at the same time, and notably that of avoiding as much as possible malarious regions in general and shortening to the utmost the stay of people or troops in them.

In the army medical service the muriate of quinine is exhibited in place of the sulphate, as the former is more soluble.

Treatment of Certain Tumors of the Mouth by Chlorate of Potash.—M. Dumontpallier presented three cases of tumors of the gums and tongue, tumors of doubtful growth and appearance as regards malignancy, in which the chlorate of potash long continued by local application as well as by the mouth in doses of four grams or a drachm a day, had a most happy effect upon these bucco-lingual affections. This treat-

ment ought to be continued for about three months and should only be begun after assurance of the functional regularity of the kidneys, which, with the salivary glands, are the principal organs of elimination of chlorate of potash.

M. Reclus said in conclusion that he had experimented with chlorate of potash for several years past and had obtained good results in cutaneous cancrs; on the contrary, the ameliorations obtained in cases of cancr of mucous membranes were always followed by relapse.

The academy then adjourned.

AMATEUR SURGERY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: As a young man with surgical aspirations I am distressed by a letter of Dr. Robert Abbe published in your issue of March 21st instant.

I am bewildered by the rhetoric, but that concerns me only as a matter of taste.

Dr. Delavan has to see what he thinks of himself with Littré's "derogative" definition of amateur which Dr. Abbe has shown he had in his mind and has brought to his attention.

My thirst for fame and incidentally my substantial interests are prompting me to hope for "grave operations" in my career as a surgeon, but this plain tale has put me down. "No man," quoth he, "of mediocre talent or training should attempt operations involving great risk to human life and obviously beyond his depth."

This was said to Dr. Delavan and not to me, so I do not resent it, but am thrown into a state of great concern by questions of mediocrity of talent. How shall I decide if these things be too great for me?

May I ask Dr. Abbe how he reached a state of assurance in similar condition of incipency and finally qualified for his first grave operation?

I had hoped for the experience of a grave operation and the price of it, but the ethical argument that I now hold with myself puts this in abeyance until my right is established or my undoing fixed by disabling mediocrity.

I overheard an operating-room full of surgeons some years since discuss the rash act of a young Boston physician who committed suicide because of his conviction that he had omitted some possible remedy in treatment of a patient who had died.

Dr. Abbe's whilom preceptor remarked jocosely that if such a precedent were established there would be a rapid thinning of the ranks of the profession. "The squirming" of mediocre persons who listened to Dr. Abbe's recent paper and the congratulations of non-mediocre persons offered on the occasion show that there is some touch by which a man knows his classification. Now this may be the "training" of which the letter speaks, and if this be so and it is not a divine afflatus, I shall sue my late preceptor for malpractice.

I hope I do not squirm when papers are read, as that seems an indication of mediocrity that is not modest but does grave operations. I may, after I have performed the functions unworthily, squirm and have a conviction while squirming, but that is all too late.

I must insist upon some of the elect giving me the crucial test that I may know how, with no chance of hospital service unless I am of a college faculty and little chance of private practice because the hospitals and dispensaries treat the middle class gratuitously and the rich will none of me for my lack of hospital experience, I can bear the consciousness of mental endowment, do grave operations, and reap the sheaves.

DISCOURAGED.

March 22, 1896.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 28, 1896:

	Cases.	Deaths.
Tuberculosis.....	247	128
Typhoid fever.....	8	3
Scarlet fever.....	123	8
Cerebro-spinal meningitis.....	3	8
Measles.....	573	35
Diphtheria.....	228	31
Small-pox.....	0	0

Amenorrhœa.—The general causes are: Exhausted state of the system due to phthisis, anæmia, malaria, syphilis, or nervous prostration; poor food, bad hygiene, or overwork; mental emotion, as joy, sorrow, or fear of pregnancy; physical shock, obesity, plethora, change of residence. The local causes are: Occlusion of the genital canal, the result of traumatism during labor or adhesions resulting from operative procedures or caustic applications; superinvolution of the uterus following labor; the second stage of chronic areolar hyperplasia; sudden suppression from cold; removal of the uterus or its appendages.—ASHTON.

Test for Sugar.—When percentage is very small and there is a doubt that the reduction of Fehling's solution has resulted from uric acid or from creatinin, filter the urine first three times through animal charcoal. If Pavy's ammoniated cupric test is used instead of Fehling's, a larger quantity must be employed and the urine added to the depth of two inches in the tube. Boil the upper portion of the mixture, which loses its blue color if sugar be present.—ROBERTS.

Non-Tuberculous Ulcers in Tuberculous Patients.—Claude reports two cases of ulcerous condition of the tongue in consumptives, neither of which were produced directly by the Koch bacillus. One was a granulated process and the other was caused by secondary micro-organisms in the mouth of a cachectic.—*Gaz. Méd. de Paris*, February 1st.

Lectures of Benjamin Rush.—Rush Medical College, Chicago, has recently come into possession of a volume of notes in the handwriting of a medical student who attended the lectures of Dr. Benjamin Rush in 1784. The volume, quite antique and dilapidated in appearance, contains two hundred and seventy-eight pages written in a clear hand and presents a brief outline of the symptoms of disease with the modes of treatment as conducted by the distinguished lecturer. Scribbled on several of the pages are opinions, quotations, and considerable matter irrelevant to the subjects of the lectures. Advice to students as regards character, behavior, dignity, and avoidance of quackery, seems to have been as needful a century ago as now. A lecture is devoted to this subject. This interesting volume was for many years early in the century the property of Dr. John K. Briggs, of Dedham, Mass., and was presented to Rush Medical College through Charles C. Hyde, Esq., by Dr. F. M. Briggs, of Boston.—*Journal of the American Medical Association*.

Doctors' Dress.—L. R. C. P., writing to the *Medical Times and Gazette*, thinks doctors should have a uniform by which they would be known in public. The *Utica Daily Press*, commenting upon the stand recently taken by the MEDICAL RECORD, agrees with us that physicians have no general desire to label themselves by any badge or uniform.

MIDDLETON-GOLDSMITH LECTURES¹—ON THE RELATIONSHIP BETWEEN INFLAM- MATION AND SUNDRY FORMS OF FI- BROSIS.

By J. GEORGE ADAMI, M.A., M.D. CAMB.,

PROFESSOR OF PATHOLOGY, M'GILL UNIVERSITY, MONTREAL.

Lecture II.—Conclusion.

PASSING NOW to the arteries, we find that just as the muscular walls and pericardium of the heart are nourished by the coronary vessels, so the media and adventitia of the arteries are nourished by the vasa vasorum, whereas in health the intima appears to be non-vascular. Indeed, where it is well developed, the internal elastic lamina appears to constitute a boundary line between the vascular and non-vascular areas of the arteries. We are forced, I hold, to regard the intima as nourished from the blood circulating within the arteries.

The diseases to which the arterial walls are subject are closely comparable with those of the heart. There can, for example, be undoubted inflammation; we may even have collections of pus cells separating the intima from the media, although this is very rare and is always secondary to a purulent mesarteritis, the pus cells wandering into the intima from the vessels of the media. Even in cases of septic embolism or thrombosis, necrosis is the first noticeable change in the intima, and the invasion of leucocytes appears to be associated with the later inflammation of the media and adventitia. Rather more frequent is an acute productive inflammation, seen especially in the first portion of the aorta. This appears to be secondary to similar verrucose, subacute, and ulcerous inflammation of the aortic valves. It is characterized by the development of almost papillomatous or warty processes projecting into the lumen of the aorta, and these are richly cellular and also vascularized from the vasa vasorum. They are often covered by a layer of coagulum.

But these obviously inflammatory conditions are relatively rare. The most common form of arterial disease in the larger arteries is that termed by Virchow *endarteritis chronica nodosa sive deformans*, the arterio-sclerosis of Lobstein, or atheroma. I need not here enter into statistics concerning its frequency, or take up your time by details concerning the forms that it may assume. I will accept Dr. Councilman's classification,² simply modifying his terminology to indicate my doubts as to the endarteritic or inflammatory nature of the conditions. With him, therefore, I would distinguish (*a*) a nodular arterio-sclerosis, (*b*) senile arterio-sclerosis, and (*c*) diffuse arterio-sclerosis; and would with him acknowledge that these three forms merge one into the other. For our purpose, as throw-

ing light upon the nature of the condition, the nodular form, the true *endarteritis nodosa* of Virchow, is that to which I would more especially call your attention.

The process begins by the development of semi-transparent, almost gelatinous, plaques here and there upon the walls of the aorta and larger vessels, most often in the neighborhood of and around the orifice of some side branch. Where the process is older the plaques are found firm, dense, and of almost cartilaginous hardness, and with this stage the deeper regions of the plaques exhibit manifest degenerative changes, passing on to the deposit of calcareous salts in the necrobiotic substance.

If we examine these plaques we are struck by the following peculiarities: (1) The endothelium over the plaque is continuous and apparently unaffected; (2) the new tissue is laid down regularly in layers parallel to the endothelium; (3) the connective tissue of the intima in the immediate neighborhood of the plaque passes imperceptibly into the hypertrophied connective tissue forming the plaque; there is no boundary line to be made out; (4) the oldest layers of the plaque are evidently those nearest to the elastic lamina, the most recent are beneath the endothelium and farthest away from the vasa vasorum of the media; and (5) the plaque is devoid of vessels save and except in those cases in which there is an evident attempt at the removal of the necrosed atheromatous material, and vessels penetrate into the atheromatous mass from the media in a manner comparable with their passage into a thrombus. Such passage, it will be recognized, is of purely secondary nature—the fibrous tissue has developed and undergone degeneration before it takes place.

The picture presented is not one usually associated with inflammation. The picture is rather what we should expect to find in an orderly connective-tissue hypertrophy, while the degeneration appearing in the deeper layers is what might be expected to occur in a non-vascular area in which layer after layer of connective tissue cut off these deeper parts from their ordinary source of nutrition. Indeed, the sharp definition of the necrosed and calcareous tissue at the internal elastic lamina is often very remarkable and would appear not only to afford a proof of the correctness of the view that the intima is nourished from the interior of the artery, but also would suggest that the internal elastic lamina performs a very definite function in separating two vascular areas.

This, however, is not the whole picture. Constantly accompanying and indeed preceding the changes in the intima, there is to be recognized an injury or degeneration of the outer coats, whether of specific, inflammatory causation (as in cases recorded by Thoma and Peabody), or whether due to more obscure alterations in nutrition associated with disturbances of the vasa vasorum. In many cases these small vessels are congested and present either an infiltration of small round cells in their immediate neighborhood or the development of surrounding fibrous tissue. The muscle fibres of the media frequently exhibit hyaline and other degenerative changes, and there may be some replacement fibrosis,

¹ Delivered before the New York Pathological Society.

² Councilman: "On the Relations between Arterial Disease and Tissue Changes." Trans. Association American Physicians, vi., 1891, p. 179.

or again evidences of more extensive failure of nutrition and of necrobiosis in the shape of small areas of calcareous deposit. That is to say, the media is very definitely affected and, as Thoma's experiments have fully proved, each plaque of overgrowth of the intima corresponds to a localized giving way of the arterial wall, to a localized slight bulging of the same; for by injecting affected arteries with paraffin under a pressure of one hundred and sixty millimetres of mercury, Thoma obtained a smooth cylindrical mould

FIG. 1.—Section of the Aorta from a Case of Nodose Arterio-sclerosis. 1, Thick layer of hyperplastic connective tissue lying immediately beneath the endothelium; 2, hyaline and fatty degeneration of the lower layers of the intima; 3, internal layers of the media, staining poorly and having a hyaloid appearance; 4, outer layers of the media—cellular infiltration around the vasa vasorum.¹

showing no signs of depressions corresponding to any projecting plaques; the hypertrophied intima fills and obliterates the slight bulgings or pouches of the outer coats. However produced, there can be no question that we have here to deal with a compensatory hypertrophy of the intima.

In the diffuse form also Thoma has demonstrated that the growth of connective tissue in the intima has a similar compensatory nature.

Is this process to be denominated an inflammation?

Thoma and his pupils have shown that a thickening of the intima which they regard as strictly analogous is to be met with in the arteries of amputated limbs, in the portion of the aorta between the ductus Botalli and the offset of the umbilical arteries immediately following upon birth, in the uterine arteries after menstruation has set in, and still more clearly after childbirth; so to a less extent in the splenic arteries. All these latter cases must surely be classed among physiological rather than pathological reactions. Surely it is impossible to class a normal constant change, such as the overgrowth of the aortic intima following upon birth, as an inflammation. Nevertheless Thoma refers—or referred—to all these as conditions of compensatory endarteritis. But if he is right—and I do not see that he is not—in grouping all these cases, physiological and pathological, into one common class and ascribing to all a common causation, then not one ought strictly to be regarded as of inflammatory origin.

Thoma would explain his compensatory endarteritis according to the following law, namely, that the condition is to be ascribed to a slowing of the blood current. If this slowing be not arrested by a contraction of the media and consequent narrowing of the artery, leading to more rapid flow, then there occurs a new growth in the intima which leads to the same end—causing the lumen to become narrowed and the current to be restored to its normal rate.

¹ For this specimen and that from which Fig. 2 has been made I am indebted to Dr. G. H. Mathewson, who is studying the cases of arterio-sclerosis occurring at the Royal Victoria Hospital, Montreal.

He thus holds, and in this we must agree with him, that the primary lesion in arterio-sclerosis is a defect, a giving way, of the media, due to loss of elasticity however produced—and the only factor that he judges capable of explaining both the physiological and the pathological cases of connective-tissue overgrowth in the intima, and which is common to all cases, is relative slowing of the blood current. It is difficult to follow his explanation of the mechanism whereby such slowing induces the hyperplasia of the fibrous tissue. Even if this slowing leads, as he indicates, to functional disturbance of the vasa vasorum, I cannot see how these vessels influence the nutrition of the intima. As I have said, I cannot find evidence that in healthy arteries or in the earlier stages of arterio-sclerosis any branches of these vessels pass into the intima. The process within the "bandelette" (as French histologists term the internal elastic lamina) appears to be at first sharply cut off from that occurring outside the same, and to be of a different nature—the new growth does not appear to develop from the neighborhood of the "bandelette" and in the proximity of branches of the vasa vasorum entering the intima, did they exist (save, as I have already stated, secondarily to degenerative changes), but occurs at a region farthest away from such branches. At most a thin and in general hyaline degenerated layer may frequently be found lying between the calcified atheromatous mass in the overgrown intima and the internal elastic lamina. This would indicate that a small amount of nutrition is derived from the media. On the other hand, the examination of numerous sections would indicate that after the degeneration of the lower layers of the intima and the deposit there of a dense calcareous mass, growth still occurs actively and new layers become formed immediately beneath the endothelium. Were the main nutrition from the vasa vasorum of the media this would not be possible, and malnutrition in consequence of disturbances in these vessels would lead to the production of wedges of degeneration extending toward the lumen, rather than to plaques of degeneration lying deep down in the thickened intima close to the internal elastic lamina.

Thus I cannot but conclude that disturbances in the vasa vasorum are incapable of immediately originating the changes that occur in the intima. There may be fibroid, hyaline, and necrotic changes in all the coats of an artery, but the sequence of changes in the intima does not maintain a strict dependence upon

FIG. 2.—Section of the Aorta from a Case of Nodose Arterio-sclerosis, to show the bulging and thinning of the media, prepared by Dr. Mathewson; magnified 8 diameters. The section shows also the hyaline degeneration of the deeper layers of the overgrown intima, and the persistence of a fine layer of less altered intima tissue immediately beneath the media. The media in this case showed evidences of calcareous degeneration in patches, with some hyaline change.

and direct association with the sequence in the media and adventitia.

Alterations in the vasa vasorum failing to explain the new growth, I am compelled to fall back upon altered tension as a factor to be adduced in partial explanation of these cases of increased growth. With Thoma we may possibly also call in the agency of the sensory and trophic nerves as governing the growth, but here we enter further upon speculative ground. They may play—they probably play—an active part, but we have no direct evidence that they do.

The most that we can safely urge is that with relative expansion of an artery or portion of an artery there must be an altered tension acting upon the cells of the intima of the affected region—that accepting the view

FIG. 3.—Section of an Artery of Medium Size, from the collection at McGill University. [This had been employed as a test specimen for the class and its label removed so that its exact origin cannot be stated.] 1, Intact endothelium; 2, layers of fibrous hyperplasia; 3, hyaline degeneration of the fibrous tissue; 4, layer of calcareous degeneration lying in immediate proximity to 5, the internal elastic lamina, somewhat swollen; 6, media presenting no distinct evidences of disease.

FIG. 4.—Section of Coronary Artery from a Case of general Arterio-sclerosis, to show the persistence of a layer of but slightly altered connective tissue between the internal elastic lamina and the layer of calcareous degeneration. In this artery there had evidently been, as indicated at 4, two successive periods of sclerotic thickening of the intima, corresponding to a giving way of the media in two places.

that the intima is nourished from within the lumen, anything which will lead to increased passage of the blood plasma into the subendothelial layers of the intima may at the same time lead to an increased strain upon the connective-tissue cells of the intima, and so to increased proliferation of the same.

If this be so, we may have another ground than the histological appearance for regarding the condition as non-inflammatory; we have to deal with a stimulus rather than injury to the cells of the intima, and may see in the fibrous hyperplasia a response to a physiological stimulus rather than a reaction to injury. In any case with our present knowledge, limited as it is, I would urge that the non-committal term of arterio-sclerosis is preferable to that of chronic endarteritis. Than this latter the term chronic arteritis is more acceptable, for in connection with the artery as a whole as distinguished from the intima there is in the giving way and thinning of the media evidence of injury, and in the intima as well as in the media, and it may be in the adventitia also, evidence of repair—of the artery as a whole, not of the intima; an arteritis, not an endarteritis.

The distinction I admit is fine drawn, yet I am compelled to acknowledge that it exists. I cannot acknowledge a physiological inflammation, and if, as Thoma points out, the initial process is identical in physiological overgrowth of the intima and that occurring in arterio-sclerosis, then the latter process must be regarded as functional. Were some irritant discovered capable of directly inducing the hyperplasia of the intima, the case might present a different facies. That such an irritant exists is, it seems to me, highly improbable. The peculiar contrast between the pulmonary and the systemic arteries in their liability to arterio-sclerotic changes is strongly suggestive of the action of differences in the circulation as explaining the contrast and not of the action of any irritative component of the blood.

I do but suggest this, and suggest it most tentatively. I shall feel rewarded if the suggestion leads to increased study into the phenomena underlying some

of the commonest and most important forms of connective-tissue overgrowth. We are so woefully ignorant of the causation of such common conditions as chronic valve disease and arterio-sclerosis that I feel that, even if the views here enunciated originate strong and successful opposition, the stimulus they may have given to further investigation will be an ample reward.

The whole matter, as it appears to me, resolves itself into this: "Can we regard fibrous connective tissue as following the same laws as the higher tissues and so as undergoing hypertrophy in consequence of increased work or increased strain brought to bear upon it?" If we can, then it would seem that we can divide off an important series of fibroses from the huge class of inflammatory fibroses. If we cannot, then we must continue to regard all fibroses save the neoplastic as chronic "itides."

Provisionally, therefore, I would divide the various forms of fibrosis as shown in the diagram, namely:

A. Of inflammatory origin:

1. Replacement.
2. Productive.
3. Combined productive and replacement.
4. Neoplastic.

B. Neoplastic, of undetermined causation:

1. True fibromata.

C. Of functional origin:

1. Lymphatic.
2. Venous.
3. Arterial.

There are very many individual cases of fibroid change that I have not discussed in these two lectures. To have done so would have consumed too much time and would have carried us still farther into conjectural

FIG. 5.—From a Section of the left Ventricle of a Patient dying from aortic stenosis with general arterio-sclerosis, to show mixed dystrophic (a) and periarterial fibrosis (d).

regions. But the cases that I have brought before you represent, I believe, the main types of fibrosis; and those not here taken into consideration will, I believe, fall into one or other of the main classes here indicated.

In conclusion I beg, Mr. President, to thank you and all the members for your great courtesy in enduring so patiently the long discourse that I have inflicted upon you, and once again to thank you for the honor you have conferred upon me in inviting me to deliver these lectures.

Original Articles.

THE CUTANEOUS MANIFESTATIONS OF DIABETES.¹

BY PRINCE A. MORROW, M.D.,

SURGEON TO THE CITY HOSPITAL, ATTENDING PHYSICIAN TO THE SKIN AND VENEREAL DEPARTMENT, NEW YORK HOSPITAL.

WHATEVER may be the theory of the formation of sugar in the economy, the phenomena of diabetes are essentially those of disordered nutrition. The continued presence of sugar in the blood changes its chemical qualities and modifies its vital properties in such a way as to render it inapt for the normal nutrition of the tissues. Of all the organs of the body the skin is perhaps the most conspicuously influenced by this impaired nutrition. As a result of the trophic disturbance its capacity of resistance becomes enfeebled, it acquires a special vulnerability to irritant influences, and it is peculiarly prone to inflammation, suppuration, and gangrene. In addition to functional and sensory disorders, almost every form and degree of inflammatory reaction, from a simple erythema to the highest grade of dermatitis may be met with in the course of diabetes.

These changes in the skin are more or less intimately related to glycosuria as a determining cause. According to the closeness of this etiological connection and the frequency with which they develop, they may be divided into two classes.

The first class comprises affections which are impressed with certain special characters which reveal their diabetic origin and nature; they are sufficiently common to entitle them to a definite place in the symptomatology of diabetes. Of these may be mentioned certain functional and structural lesions of the skin, pruritus, diabetic erythema, eczema, balano posthitis, phimosis, furuncles, carbuncles, and gangrene, to which may be added a comparatively recently recognized dermatosis, xanthoma diabeticorum.

In the second class may be placed affections which occur incidentally and with comparative infrequency. Their association with diabetes cannot, however, be regarded as a coincidence merely; they exhibit certain peculiarities in their clinical behavior, especially in their tendency to recovery or retrogression according to the fluctuation in the amount of sugar present, which clearly indicates some etiological connection. Among the most important may be mentioned acne cachecticorum, chronic papular urticaria, impetiginous and lichenoid eruptions, psoriasis, dermatitis herpetiformis, herpes zoster, mal perforant, erysipelas, and dermatitis diabetica papillomatosa.

So common and characteristic are affections of the first class that they are recognized by French authors as a separate group under the designation of *diabétides*, on the ground that they bear the same relation to the constitutional disorder as do the syphilides and scrofulides to their respective diatheses. By other writers they are identified as *dermatoses diabeticae*—a name sufficiently specific to indicate their origin.

Perhaps the most characteristic expression of diabetic disorders of the skin is found in the genital region, from the anatomical disposition of the parts which expose them to contact with the saccharine urine. The urine rapidly undergoes fermentation and favors the production of a growth of cryptogamic vegetation, which appears as white deposits on the surface or between the epithelial cells. These deposits are formed of rounded or oval spores and a mycelium made up of short or long branches, sometimes articulated. They are especially apt to occur beneath the

prepuce of the clitoris and in the sulcus between the labia majora and minora in the female, and along the sides of the frenum, and the glando-preputial sulcus in the male. They are considered pathognomonic of glycosuria. P. Ernst found in addition to the saccharomyces all possible forms of spores, among the micrococci, the staphylococcus aureus, and bacilli of the group of the bacillus coli, etc.

Apart from their clinical interest the diabetic dermatoses are most important from a diagnostic point of view. Many of them are so typical as to enable the practised observer to identify the etiological factor from the objective characters of the lesions.

Lasègue, a distinguished French physician, has said: "A singular thing is that the general practitioner rarely discovers diabetes. Most often it is ferreted out by the skilled specialist *à propos* of some special symptom. The patient consults an ophthalmologist for a commencing amblyopia, a neurologist for painful neuralgias, a dentist for an expulsive gingivitis, a dermatologist for a genital eczema or carbuncle, or a syphilographer for a balano-posthitis or a phimosis." Personally, I may say that I have diagnosticated diabetes in at least half a dozen cases, four men and two women, from the optical characters of their cutaneous lesions. These persons were unconscious diabetics, and came to consult me for their local trouble without the slightest suspicion of the existence of a constitutional disorder.

Asteatosis and Anidrosis.—One of the earliest cutaneous manifestations of diabetes is functional disorder of the sebaceous and sweat glands. In the majority of cases asteatosis and anidrosis, more or less complete, are observed. The diminution in the quantity of the sweat is sometimes most marked, the total amount being reduced to one-half or one-fourth of the normal quantity. There may be not only a quantitative but also a qualitative change in the secretion from the elimination of glucose, which has been observed in the form of a white powder on the skin (Vogel). Exceptionally the glandular disorder may be expressed in the opposite condition of hyperidrosis. In one of my patients the perspiration was so profuse as to necessitate changing of the underwear two or three times a day. Many cases of localized hyperidrosis and unilateral sweating have also been recorded. These latter phenomena are doubtless the result of a vasomotor disturbance due to an impression upon the nerve centres or upon the peripheral nerves in the skin. These functional disorders are commonly attended with trophic changes. The skin loses its soft, supple feel and becomes dry, harsh, and rough and the seat of furfuraceous desquamation. Sometimes exfoliation of the epidermis occurs in large flakes, and is so abundant as to simulate dermatitis exfoliativa. H. H. Horden² reports a typical case of universal pityriasis rubra with alopecia. A pint and a half of scales were exfoliated per diem. There was no gout, rheumatism, or evidences of other constitutional disorder than the diabetes.

Paræsthesia.—Another habitual expression of diabetes is sensory disorder. Paræsthesias and perversions of sensation, usually characterized by the most intense pruritus, may be present at an early stage. That distressing condition, pruritus vulvæ, is frequently associated with structural changes, and will be considered in connection with genital eczema. The sensory disturbance is not limited to the genital sphere, but may be manifest in remote parts, as on various portions of the trunk and lower limbs. It is sometimes so pronounced as to render the pressure or friction of the clothing insupportable. Pétér cites cases in which itching over the whole surface of the body was intolerable. As a result of the scratching there

¹ Read before the New York Academy of Medicine, April 2.² London Lancet, 1893, p. 1,056.

were numerous excoriations with papules of prurigo upon an erythematous base.

Defluvium Capillorum.—Trophic disorders of the sebaceous and hair follicles are seen in thinning and loss of the hair. It has been often observed that the hairs of the scalp as well as of the general surface became dry, fragile, and loose, yielding to the slightest traction. Numerous cases are cited by Grauffon,¹ Lapiere,² and others in which alopecia more or less complete was observed in the course of diabetes. In August, 1894, I was consulted by a patient for syphilis, on whose scalp and body there was not a vestige of hair. The universality of its loss excluded syphilitic alopecia. Moreover, it was found that the alopecia began before the inception of syphilis. The discovery of five per cent. of sugar in the urine with the patient's statement that he had known of the existence of sugar in his urine for at least five years rendered it probable that the alopecia was due to the diabetes.

Paronychia Diabetica—Falling of the Nails.—Trophic disorder may also be manifest in loosening and falling of the nails or atrophy of these organs. The process commonly begins in the matrix of the nail or in the periungual fold as an indolent subacute inflammation, with slight redness and tumefaction. Suppuration sets in with a discharge between the skin and the nail—the proximal border of the nail is uplifted and separated from its bed from behind forward and the nail finally detached. Follet has reported a case in which the nails of a diabetic woman fell out without inflammation. In some cases the nail is reproduced but is rudimentary, with a rough rugous surface. In advanced cases the nail bed may become the seat of gangrene. Falling of the nails, like that of the teeth, may occur at an early stage. Verneuil and others have reported numerous cases. In three cases described by Auché³ he says, "the vasomotor and nutritive troubles were characterized by œdema, a smooth and glossy state of the skin, mal perforant, glandular and ungual dystrophies, spontaneous fall of nails, and cutaneous gangrene." According to Kaposi paronychia diabetica is more apt to affect the great and little toes, sometimes the middle toes. In his cases gangrene did not follow the fall of the nails.

Eruptive Disorders.—Among the eruptive diabetic disorders, erythema and eczema, affecting more especially the genital and perigenital regions, frequently occur. In all cases sensory disorders, such as pruritus, heat, burning, etc., precede the development of the eruptive phenomena. In many cases, doubtless, the lesions are traumatic, the result of rubbing and scratching the parts to relieve the atrocious itching, which may be constant or paroxysmal in character. The dermatitis is usually ascribed to the irritating contact of the urine. In many cases, however, it appears on surfaces which are not exposed to such irritation. Hardy says that he has frequently seen erythema occupy regions of the body to which the urine could not possibly have reached, as the mammary region and suprapubic folds of fat females. Fritz⁴ reports cases of fugitive erythema occurring in patches over different parts of the body.

Pruritus is usually more intense in females, from their nervous temperament and the greater extent of the surfaces involved. It may constitute the only symptom of the diabetic disorder. Usually, however, it is attended with congestion and redness of the vulva and neighboring parts. This erythematous condition may mark the acme of the inflammatory process, or it may take on the more active symptoms of eczema with exudation.

Eczema Vulvæ is characterized by an intense redness with tumefaction of the labia. The surfaces are often excoriated by scratching, and discharge a thin gluey secretion. The inflammation not infrequently involves the mucous membrane of the vagina. Whitish deposits or thin crusts consisting of parasitic growths with desquamated epithelial cells may often be found on the flat surfaces and between the labia.

In his classic description of the genital diabetides Fournier describes a chronic form ordinarily succeeding the acute. The inflammation is not limited to the vulva, but involves the perineal and anal region, the inner sides of the thighs, and may extend upon the abdomen. The skin is of a brownish-red, almost livid color, the surface secreting and desquamating, the tissues thickened by a hyperplastic infiltration resulting from the incessant scratching. There results a hypertrophic vulvitis, and the labia become swollen and thickened to two or three times their normal volume. The vagina is of a vinous-red color and the introitus so narrowed by the infiltration as to render the introduction of the speculum difficult.

In addition Winckel describes furuncles of the vulva and phlegmonous vulvitis.

While diabetic eczema of the female genitals presents many features in common with ordinary eczema, it may be differentiated by certain peculiarities. The hyperplastic infiltration is more marked, the color is of a sombre red, the secretion is less abundant, the surface often presents a dry, glazed appearance with a continual desquamation of thin whitish crusts of sebaceous matter and parasitic growths. The subjective sensations are more intense.

Diabetic Disorders of the Male Genitals are usually expressed in the form of balanitis or of balanoposthitis. In the majority of cases pruritus constitutes the first symptom. The eruption usually begins as an erythema of the meatus urinarius and spreads upward over the glans.

Balanitis.—In a patient under my observation this erythematous redness, involving the anterior three-fourths of the glans with an occasional outcropping of erythematous patches on the corona and sulcus, persisted for several months as the sole objective symptom. In this case the glans was habitually uncovered. Isolated balanitis is, however, rare and is seen only in circumcised subjects and men with short prepuces.

Balano-Posthitis.—In the majority of cases the inflammation extends over the glans and involves the preputial mucous membrane, constituting balano-posthitis. A long narrow prepuce and lack of cleanliness favor this complication. The surface of the glans and inner prepuce become inflamed and tumefied and the seat of desquamation. As a result of the continued irritation the swollen mucous membrane becomes cracked and fissured, the linear clefts corresponding to the long axis of the organ. The progressive thickening of the prepuce and its loss of elasticity finally determine phimosis. The typical features of diabetic phimosis were shown in a patient, aged forty, who came under my observation in July, 1892. The preputial orifice was contracted to such a degree as to prevent the free passage of the urine. The prepuce was infiltrated, inelastic, and felt like a cartilaginous case, showing at its orifice the beginning of fissures and clefts radiating backward. Even after the induration had subsided an attempt to retract the prepuce opened up the fissures, causing them to bleed. The irritation had been so long continued as to cause implication of the lymphatics, which could be felt as hard cords along the dorsum. Two of the glands in the left inguinal region became inflamed and suppurated. These were aspirated and finally opened by a free incision. Some months later this patient contracted a chancre of the prepuce followed by a severe type of syphilis. It is

² Thèse de Paris, 1879.

³ Arch. de Méd. Exper., 1890.

⁴ Gazette des Hôpitaux, 1862.

worthy of note that the diabetic condition markedly improved under specific treatment.

Genital Eczema.—The inflammation, instead of being limited to the glans and prepuce, may extend to the neighboring parts and assume the characters of a chronic eczema, as in the following case: An old gentleman was referred to me in May, 1890, by the late Dr. Fordyce Barker. He had an erythematous eczema of the glans and preputium accompanied by intense itching, which was recognized as diabetic. His foreskin was short, leaving the glans entirely uncovered. Under the influence of appropriate treatment the local trouble disappeared. There was a slight redevelopment in March, 1893, but of short duration. In the spring of 1894, when he presented himself again, the local affection was more extensive, involving the skin of the penis and scrotum. His urine was found to contain six per cent. of sugar. Under the influence of codeine, a strict diet, and local treatment, the amount of sugar was reduced to less than one per cent., and the local trouble was practically cured. When he went to the country in June he abandoned his diet and treatment. He returned the latter part of August with a marked aggravation of his general and local trouble, with the addition of new eruptive phenomena in the shape of a number of large papular lesions distributed over the abdomen, the buttocks, and the lower extremities. All of these underwent involution in the course of two or three weeks, with the exception of a few lesions on the thigh, buttocks, and over the ankles. In two places, on the thigh and buttocks, the absorption of the papular elements was followed by a superficial gangrene. Those over the ankles were converted into deep ecthymatous ulcers, which became gangrenous and were two or three months in healing. There was also a profuse eruption of lichenoid papules in both genito-crural folds, extending down the inner sides of the thighs. The eczema involved the glans, the prepuce, the skin of the penis, the scrotum, perineum, and anus. The glans was swollen, with marked induration and thickening of the integument of the penis and scrotum. The prepuce, which was abnormally short, was thickened, inelastic, and could not be drawn forward. The surface of the glans and reflected prepuce was covered with a parchment-like membrane which was continually reformed. This thin white pellicle could be detached without leaving bleeding points and was analogous to that already described in connection with eczema of the vulvæ. In this case the eczema continued for several months with but slight modification. Its persistence was doubtless due to the age of the patient, eighty-three, and his loss of control over the bladder. After the act of urination was completed there was dribbling of urine, which kept the dressings continually soiled. The use of a rubber dressing aggravated the eczema. A dressing recently brought to my attention would have answered admirably in this case. It is made by McKesson and Robbins, and consists of muslin or gauze impregnated with stearate of zinc in combination with an antiseptic substance. I have kept it immersed in water for several hours without its imbibing the least moisture.

Diabetic eczema of the male genitals may be readily distinguished from ordinary eczema. In the latter the inflammation is more acute, the surface of a brighter red, often exulcerated, the weeping and discharge are much more profuse and often of a seropurulent character. Besides, an ordinary eczema rarely begins on the glans penis and is still more rarely limited to the glans and prepuce.

Diabetic balanoposthitis and phimosis have a physiognomy so special that one who has observed a typical case can scarcely fail to recognize them at a glance. In the diabetic form there is an absence of

the excoriated patches and the profuse, often creamy discharge seen in ordinary balanitis. The inflammatory process is subacute; there is a dry, glazed, often cracked condition of the surface, with scanty secretion; a progressive thickening of the integument, ending in a local sclerema, inelasticity, and atresia of the preputial orifice. It is to be noted that cases of sloughing and gangrene of the penis with extensive mutilation and extending up on the abdomen have been observed.

Many writers describe a herpetiform eruption closely simulating herpes, which consists of numerous small pin-head to pea-sized superficial erosions, of rounded or oval form, which desquamate and heal readily but manifest a tendency to repeated recurrence. Furuncular lesions, affecting more especially the integument of the penis and scrotum, have been observed in diabetics. Vegetations have also been noted upon the glans, the sulcus, the sides of the frenum, sometimes extending into the urethral canal. According to Aime Martin, these vegetations are distinguished from the ordinary condylomata by their greater vascularity, their brighter red color, and their tendency to bleed easily. A rare affection mentioned by Abeille is psoriasis in the form of large white plaques seated upon the indurated thickened tissues. The thickening was sufficient to cause phimosis. The psoriatic patches disappeared under improvement of the diabetic state (Leroux).

Furuncles and Carbuncles.—Of all the diabetic manifestations on the general surface of the integument furuncles are the most common and may occur at an early stage. Carbuncles and phlegmons are less frequent and usually occur at a more advanced stage of the disease.

The statement of Prout that these lesions are always of diabetic origin is too sweeping. More approximately correct is that of Marchal (de Calvi), who says "that diabetes is the etiological origin of furuncles in one-third of all cases." As regards their absolute frequency a careful writer, Von Noorden,¹ estimates "that they occur on an average in from one-tenth to one-fourth of all cases of diabetes."

Furuncles usually develop upon the neck, the back of the shoulders, or the buttocks; they may occur upon any part of the body. They are usually multiple and come out in successive crops. As many as seventy-nine have been observed in one patient. They are distinguished from ordinary boils by their multiplicity, their succession, their sanious suppuration, and their tendency to excessive sloughing and gangrene.

Carbuncles, which may be regarded as confluent furuncles, have the same seats of predilection. They are distinguished by their cribriform or honeycombed appearance, the depth of their destructive action, and their tendency to extend at the periphery and become gangrenous. They determine a more profound constitutional disturbance, an adynamic condition marked by great feebleness and prostration, which often ends fatally.

While it is generally recognized that the staphylococcus pyogenes aureus is the active pathogenetic agent in the production of furuncular lesions, the diabetic skin, from its impaired vitality, opposes a feeble resistance to the entrance of this and other pyogenic microbes, while the pathological state of the blood and tissue juices furnishes favorable conditions for their germination and growth.

Gangrene.—Diabetes creates a special predisposition to gangrene. It may be primitive and spontaneous, or it may be consecutive to slight wounds, abrasions, contusions, or some anterior lesion, as a furuncle, carbuncle, or phlegmon. It may be single or mul-

¹ "The Twentieth Century Practice."

triple, superficial or profound, limited in area or extend over a large surface. It may appear upon any portion of the body, but it more frequently occurs upon the lower limbs, from their greater exposure to traumas and the character of the circulation.

Diabetic gangrene is usually of the moist variety, frequently attended with swelling and cedema of the tissues and rapid necrosis. When the gangrene is primitive it begins as a small black patch or numerous patches disseminated here and there and is usually limited to the integument. Sometimes they are preceded by the formation of bullæ. The sphacelation may not be limited to the integument, but affect the subcutaneous tissues and produce the same results as diffuse phlegmon. Usually there is persistence of sensibility and no marked alteration of temperature. Post-mortem examination has demonstrated the permeability of the vessels. Dickinson says that degeneration of the arteries is remarkably rare in diabetic gangrene. In old persons who suffer from atheromatous changes there may be obliteration of the arterial vessels and all the phenomena of dry gangrene, such as condensation and mummification of the tissues. Exceptionally diabetic gangrene may exhibit all the characters of senile gangrene or those of Raynaud's disease. Diabetic gangrene is said never to occur in children; the youngest patient recorded in the statistics of Marchal (de Calvi) was twenty-eight years old. It is most liable to occur in fat persons, and its frequency increases with the age of the patient. Alcohol and obesity favor its development. Alcoholic diabetics are peculiarly prone to gangrene. The comparative exemption of women from this accident is largely due to their non-bibulous habits.

Kaposi has described, under the name of gangrena diabetica bullosa serpiginosa, an eruption of disseminate bullæ on an inflamed base, beneath which the skin mortified. The process was propagated in a serpiginous manner by the elevation of the epidermis and eschar formation at the periphery and cicatrization of the centre. This was continued until the patient died.

Xanthoma Diabeticorum, as its name implies, is an affection peculiar to diabetes. Of the twenty-one cases reported, eleven of which have been recorded within the past five years, glycosuria was traced as the etiological factor in all but three. Its causal connection is, moreover, shown by the involution of the eruption when the sugar is suppressed and its redevelopment with the increase of the sugar. The eruption consists of small pea-sized tumors of a rounded or conical form, discrete or confluent, some of them surmounted by a yellowish apex, which gives them a deceptive resemblance to pustules. They are of solid consistence and firm to the feel. They are essentially inflammatory, and subjective sensations of heat, burning, and itching are almost invariably present. Their most common seats are the forearms, buttocks, and knees, from which they may gradually extend over the extensor surfaces, the scalp, face, trunk and abdomen. In some cases the eruption is universal. The eruption may remain stationary for months or years, and then undergo rapid involution, leaving no trace. It may redevelop two or three times. This affection is differentiated from xanthoma by the rapidity of its development, the character of the papules, which are firm, hard, and inflammatory; by their seats of predilection, sparing the eyelids; by its invariable presence in the form of circumscribed papules, never occurring in striae or plaques; by the subjective sensations; by the facility of its retrogression, which may be spontaneous or the result of the correction of the glycosuria.

The consideration of what may properly be termed the diabetic dermatoses has already extended this pa-

per beyond its proposed limits, so that only the briefest mention will be made of the second class of affections. Scattered through the literature of the subject will be found references to a large number of skin affections met with in the course of diabetes. Almost all of them were remarkable for their prolonged duration, the inefficiency of local treatment, and their tendency to rapid improvement when the constitutional disorder was corrected.

Chronic Papular Urticaria, the prurigo of older writers, is mentioned by numerous observers as occurring in connection with diabetes. The lesions in many cases are, doubtless, developed as the result of injuries caused by scratching to relieve the distressing pruritus. In a number of cases under Kaposi's observation, the patients were emaciated, having lost several pounds.

Eczematous, Impetiginous, and Lichenoid Eruptions are frequently cited among the concomitant symptoms of diabetes (Grauflon, Neuman and Van Stosch, Leoty, and others). Braxton Hicks¹ reports cases of generalized eczema which were refractory to all treatment until an antidiabetic medication was instituted. These eruptions are sometimes complicated with ecthyma and gangrene.

Bullous and Pemphigoid Lesions are sometimes seen upon the lower limbs; the gangrene is often preceded by the formation of bullæ which sometimes dry up into white eschars. Guntz mentions miliaria with vesicles and bullæ of the skin in a diabetic case.

Psoriasis has been often observed in connection with diabetes. The frequent coexistence of the two affections has been noted by Grauflon, Abielle, Leroux, Nielsen and Gebhardt, Poblekenoff, and others. Grube² has reported four cases of psoriasis associated with diabetes. If the theory of the parasitic nature of psoriasis be accepted, we can understand this frequent connection, as the diabetic skin furnishes a favorable ground for the development of parasites.

Acne Cachecticorum is classed by Kaposi among the diabetic dermatoses. In his cases the lesions were chiefly situated on the buttocks and the extensor surfaces of the extremities.

Dermatitis Herpetiformis.—Four cases of this affection occurring in diabetics have recently been reported by Winfield.³ In a case of xanthoma diabeticorum reported by Johnston the patient was formerly the subject of dermatitis herpetiformis. Doubtless the connection of these two diseases would be found much more frequent if evidences of sugar were sought for in all cases.

Herpes Zoster, presenting the characters of ordinary zona, but distinguished by its severity, its scarring, and the persistent neuralgias succeeding the involution of the lesions, has been observed by Vergely,⁴ who reports two cases coming under his observation, and cites one case by Barbier, two cases by Fabry, one by Pleuyette, and two by Jules and Cyr, of Vichy.

Mal Perforant.—Two cases of perforating ulcer of the foot are reported by Clement,⁵ presenting the unusual features of conservation of the sensibility, abundant hemorrhage, and formation of gangrene. Auché refers to three cases.

Purpura Hemorrhagica.—Dujardin-Beaumetz observed in his service a diabetic who had successive crops of purpura hemorrhagica. The eruption was confluent upon the lower limbs, forming in places large palm-sized placards.

Erysipelas would seem to be a comparatively rare complication of diabetes. Cases are cited by Leoty,

⁴ Prog. Médical, 1891.

⁵ Thèse de Paris, 1881.

Tardieu, Teissier, and others. In one case there were four successive attacks, the last proving fatal.

Dermatitis Diabetica Papillomatosa.—Under this title Kaposi describes an inflammation of the skin occurring in glycosuria, characterized by the development on an inflamed base of nodular excrescences in patches which partly disintegrate into ulcers with undetermined borders.

Finally may be mentioned **bronzed skin**. In a recent number of the *Wiener Medicinische Blätter*, 1896, p. 101, v. Harndt describes a bronzing of the skin peculiar to diabetes, which he claims is differentiated from Addison's disease by the immunity of the mucous membranes from pigmentation. The melanoderma is most pronounced on the face, lips, and genitals.

THE EARLY MANAGEMENT OF CONGENITAL CLUBFOOT.¹

By LEWIS A. SAYRE, M.D.,

NEW YORK.

WITHOUT occupying your time in discussing the various theories as to the etiology and pathology of clubfoot, I will simply state what I have found by practical experience to be the best course to pursue in all cases of this unfortunate deformity, no matter what the variety may be.

Whether the case be one of varus or valgus, calcaneus or equinus, or plantaris, or any of their various combinations, the same general principles of treatment are applicable. And the time to commence their application is immediately after the birth of the child. If you are not present at the birth, then commence the treatment as soon after as you are called to see the case.

There is a prevalent idea among the profession that the treatment of clubfoot must not be commenced "until the child is old enough to stand it." This false teaching has produced such an effect upon the laity at large that they do not bring their children with crooked feet to the orthopaedic surgeon for treatment until some months after birth. Now I wish to enter my most solemn protest against this false teaching and to urge the profession at large to attempt the rectification of these deformed feet immediately after birth, or if they have not the time or inclination to qualify themselves to treat the case properly they should at once advise that the child be placed under the care of some one who will treat it properly. And this treatment should be commenced before the child is forty-eight hours old, and twenty-four is better still.

The method of procedure is for the operator to take the foot in his two hands and gradually but very gently press it around toward the normal position. As this is done you will observe the toes and front part of the foot to become blanched as white as snow and apparently perfectly bloodless. If retained in this position too long, of course sloughing would necessarily follow this obstruction to the circulation. Therefore, after holding the foot in this improved position for a few seconds only, you relax your hold upon the foot, when it will immediately recede toward its former deformed position, and as it does so you will observe the gradual return of the pink color and the natural circulation to the foot and toes.

If both feet are deformed (as is generally the case), you can take the other foot and treat it in the same manner as you did the other, while the first is being restored to its previously deformed condition.

Repeat these various manœuvres a number of times and carefully instruct the nurse how to do the same, and see that she does it properly every few hours day and night.

¹ Read before the Medical Society of the County of New York, March 23, 1896.

In addition to the improvement gained by frequent manipulation of the foot or feet, great advantage may be gained by covering the foot and leg with a very soft flannel bandage (leaving the toes exposed for observation), and then applying a strip of adhesive plaster partly around the foot and drawing it as far in the right direction as can be borne without interfering with the circulation, which can be judged by watching the color of the toes, and then securing the plaster by a snugly applied roller bandage. This plan is to be followed up day by day, until the foot can be retained in the normal position without interference with its circulation.

To retain it in this improved position frequently requires artificial aid, and the best that can be adopted is the plaster-of-Paris bandage over a snugly fitting flannel roller bandage. It fits with perfect accuracy and therefore there is no danger of galling or chafing, and the child cannot kick it off, as it will any kind of a shoe that has ever been invented (even my own, which I have now abandoned for five years or more). If the feet are very much inverted and the gastrocnemius much contracted, then the plaster-of-Paris bandages may be continued above the knee, flexing it a little to shorten the gastrocnemius, and strongly everting the foot or feet just before the plaster sets.

In the majority of cases, by adopting the plan here suggested, the child will have his foot facing the floor by the time he is old enough to stand and then he will cure himself by exercise, sometimes, of course, requiring the slight aid of an elastic to invert or evert the toes, as the case may be.

In some cases, however, there is a structural shortening or contracture of the tissues. In such cases the contracted tissues must be subcutaneously divided and the foot immediately restored to its normal position, the wound hermetically sealed, and the parts retained absolutely immovable by a plaster-of-Paris bandage for from fourteen to sixteen days, when the wound will have healed and the exudate between the severed ends of the tendon will have become firmly united and of sufficient strength to be of practical utility in moving the foot.

What I wish to emphasize is: 1st, The necessity of commencing treatment at birth; 2d, that there is no instrument that can be compared with the human hand in rectifying the deformity; and 3d, that there is no means of retaining the parts in position equal to plaster of Paris properly applied.

If the profession at large will recognize these facts, there will be very few cases of hideously deformed clubfoot requiring tarsectomy, cuneiform osteotomy, or any of the other-serious operations now in vogue.

Methyl Green has been employed by Dr. Crouch, of Denver, as a stain for the microscopical diagnosis of diphtheria. The bacilli of cultures vary in size and besides them are certain round or oval bodies which may be made apparent. They seem to have a peculiar affinity for methyl green, with which they enter into a chemical combination changing in color from green to red. A double stain may be obtained. Dahlia has been found most useful. One part of a one-per-cent. solution in water and five parts of a one-per-cent. solution of methyl green are added to four parts of water. These bodies, though they resemble spores, are not thought to have any connection with spores. They are most abundant in young, freshly growing cultures. The writer calls them nucleoid bodies, attributing to them a nuclear nature, and believes them to possess great practical importance in the microscopical diagnosis of diphtheria. — *The American Microscopical Journal*, February, 1896.

DIPHThERITIC PALSIes AND THE USE OF ANTITOXIN.¹

BY CHARLES L. DANA, M.D.,

NEW YORK.

WHILE the treatment of diphtheria by antitoxin is a method that has been approved in all parts of the world, and is upheld by a volume of statistics whose brute force is almost overwhelming, yet there is still some degree of skepticism about its real value. Most of this skepticism is the result of profound and banal ignorance, coupled, perhaps, with some hysterical obsession in the lines of zoophilism and antivivisection. There are, however, some conservative physicians whose character and attainments we respect who still hold a position of reserve, if not of disbelief, as to the value of the method, and they advance some very ingenious explanations of the way in which the statistics that so apparently favor antitoxin are gotten up. In a recent number of *The Contemporary Review*, a gentleman by the name of Boulger has published an article in which he recites his own personal experience with diphtheria. He states that he was attacked with a malignant form of this disease, was taken to a hospital, and there injected with antitoxin of double strength. He was injected again on the second day, the course of the disease was not changed by it, and he finally got well, owing, as he believes, to the assiduous use of brandy and iron and gargles. Going home at the end of the month, he was seized rather suddenly with a very pretty type of multiple neuritis involving all the extremities. From this also he recovered. His deep conviction, however, is that the multiple neuritis was due to the injections of antitoxin, and this idea is set forth with great emphasis and eloquence in his article. The fact that this article is likely to be widely quoted by antivivisectionists and opponents of the use of antitoxin, and is likely to make some impression on the lay mind, led me to think it worth while to look up the matter. I was then further induced to do so because I had just seen a case of post-diphtheritic paralysis in a young man who had been treated with antitoxin at the Willard Parker Hospital. At the same time I learned of other cases, and particularly of one in which death occurred in a child aged four years within two days of the injections. I wrote to Dr. W. H. Park, asking his experience in this matter. His letter is given here:

"From time to time cases of general paralysis have followed diphtheria treated with antitoxin. Thus, in the last three months there have been two cases. One, an adult, had general weakness due to partial paralysis in all voluntary muscles, so that she could not walk for nearly three months; the other, a child, which developed paralysis in some of the muscles of the lower limbs. In a third case paralysis of the muscles of the eye occurred. In quite a few paralysis of muscles of palate or pharynx develops after the separation of the membrane. I think that rather more paralysis occurs now than formerly, but I believe this is due to the fact that a class of patients recovers now which formerly died. In my judgment patients who would recover without antitoxin will show less paralysis with antitoxin than without it.

"WILLIAM HALLOCK PARK."

I also wrote to Dr. Northrop, and he kindly answered that it was difficult to make a specific statement, for the reason that more patients lived to be afflicted with paralysis than formerly, but he thought that the one set of cells which was least able to avail itself of the protective influence of antitoxin was the

nerve cells. Dr. Northrop said, however, that he had seen very little post-diphtheritic paralysis this year.

The history of my own case is as follows:

Roy R—, male, aged sixteen, mulatto; occupation, porter; single; family history negative. He has had a sore throat every winter for the last few years.

On January 30, 1896, the patient was taken to the Willard Parker Hospital suffering from diphtheria. While in the hospital he complained of intense pain in the back of his head on lying down. While at the hospital he suffered from a mild type of faucial diphtheria and was treated with antitoxin in the usual way. After he had been in the hospital with the disease a few days he noticed some weakness in the legs, but he had no abnormal sensations or pains in them. Two weeks after his admission he was discharged cured and left to go to work. On the same day while running upstairs his legs began to grow weak and he was compelled to catch hold of an object to support himself. A few days later he found that he had very little strength in his legs and was unable to walk without frequently stopping and resting. The next day he was admitted to Bellevue Hospital in the service of Dr. Alexander Lambert. On February 17th, the third day after he left the Willard Parker and after the beginning of his paralysis, he was examined by me. There was no lesion of the heart, lungs, liver, spleen, or kidneys, and he complained of no pains. His arms and hands were normal. He complained chiefly of weakness in the legs and hips, more particularly on the right side. His gait was slightly unsteady on account of this weakness of the legs, but he was able to stand and to walk. He could not, however, step upon a stool. The knee jerks were absent in both legs. There was no evidence of muscular atrophy. Testing the movements of the legs showed that the anterior crural muscles and the flexors and extensors of the legs were the groups most affected, especially those on the right side. There was no anæsthesia or ataxia, but deep pressure upon the muscles caused pain. Electrical examinations showed an exaggeration of irritability to the galvanic current and an exquisite increase of the electric sensibility, a point of much importance, in my opinion, in the diagnosis of multiple neuritis in the early stages. Even mild currents which could easily be borne upon the arm or even upon the face caused great pain when applied to the affected groups of muscles in the legs. There was no paralysis of the muscles of the throat or of the ocular muscles; in fact, it was only these muscular groups mentioned that were affected. There was no involvement of the sphincters of the bladder or rectum and had not been. The patient improved very rapidly, and in a week from the time of the beginning of the disease he was apparently almost well and was discharged.

This patient illustrates very well the extremely mild type of post-diphtheritic paralysis when that affection is not located in the throat or eyes.

The Proportion of Paralyzes Following Diphtheria under any form of treatment previous to the use of antitoxin varies very much. In 937 cases collected or observed by Cadet de Gassecourt paralyzes occurred in 128, or about 13 per cent. In Roger's statistics the proportion was 16.6 per cent.; in those of Sanne it was 11 per cent. Lennox Brown in a series of 100 cases found it to be 14 per cent.; Goodall in 136 cases found it 14.7 per cent. German observers give figures ranging from 4 to 30 per cent.: Unterholzner, from 4 to 17 per cent.; Johannessen, from 12 to 30 per cent.; Hoppe-Seyler,¹ 27 per cent. The range of percentages, therefore, is from 5 to 30.

¹ Mr. Lennox Brown found the percentage in 3,848 cases to be 14 per cent. "Diphtheria," p. 260.

¹ Read before the Practitioners' Society, March 6, 1896.

The figures, however, of all large series of statistics show that the percentage is between 10 and 20. Thus, taking the figures of de Gassecourt, Roger, Sanne, Johannessen, Goodall, and Brown, we would have over one thousand cases with a percentage of palsies amounting to about one-sixth.

These figures, however, give an imperfect idea of the actual condition of things, for, in the first place, a large number of diphtheritic palsies occur two or three weeks after the termination of the disease, and after the patients have been discharged from hospitals; hence the hospital records in part are not to be depended upon. In the next place, diphtheritic paralysis occurs with greater frequency as patients get older; therefore, the ages of the patients would modify immensely the normal percentages of the palsies. According to the statistics quoted by Dr. Lewis Smith in Keating's "Cyclopedia of Children's Diseases," fifteen per cent. of cases of diphtheria occur in children under the age of nine, while, on the other hand, of sixty-eight cases of diphtheritic paralysis collected by Landouzy, seventy-five per cent. occurred after that age.

If these figures represent the clinical history of diphtheria generally, it follows that older children and adults supply the vast majority of cases of diphtheritic paralysis, and in order to get a just conception of the relative frequency of diphtheritic paralyses one must have histories of the ages of the patients. I have not been able to find any satisfactory literature bearing upon this subject. However, with what has been so far observed I conclude that in ordinary epidemics of diphtheria not treated with antitoxin the proportion of observed palsies is about fifteen per cent., and that this fifteen per cent. is made up very largely of children over the age of four years.

Paralyses after the Use of Antitoxin.—Next I take up the question of the number of paralyses that follow diphtheria, when the patient has been treated with antitoxin. In regard to this subject facts are accumulating, but there are few yet that are satisfactory as regards the points of age and form of paralysis. Lennox Brown published two series of one hundred cases each of diphtheria. In the first series antitoxin was used, in the second it was not. The proportion of mortality and of diphtheritic paralyses was the same in each series, being for the mortality 27 per cent., for the palsies 14 per cent. Dr. Fürth in 100 cases had a mortality of 12 per cent. and only 4 per cent. of palsies. Dr. E. W. Goodall found that in 136 cases not treated with antitoxin there was only 14 per cent. of palsies, three cases of palsy being fatal, while in 105 cases treated with antitoxin there was 17.1 per cent. of palsies with 4 cases fatal. His statistics, which were read at the meeting of the British Medical Association in London, taken with those of Mr. Lennox Brown, form the severest indictment of the antitoxin treatment that I have seen published, and do not agree with those reached by other authors.

The most complete study as regards the palsies is that of Professor Soltmann, of Leipsic.¹ Dr. Soltmann found that in one hundred and eighteen cases treated by serum-therapy there were eighteen cases of paralysis, giving a percentage of ten. He further classifies his palsies and shows that in all cases the soft palate was affected; that in five there was paralysis of the muscles of deglutition, in three a general multiple neuritis producing ataxia. Dr. Soltmann concludes that the antitoxin does not modify the post-diphtheritic paralysis.

The statistics that I have collected as a whole regarding post-diphtheritic paralysis in cases treated by antitoxin are presented here:

Reporter.	Paralyses.	No. of Cases.
Huebner	7.9 per cent.	162
Soltmann	10 "	181
L. Brown	14 "	100
Blatt	18 "	
D'Espine	3½ or 4 "	
Fürth	4 "	
Goodall	17.1 "	100
Engel	8 "	39
Gerloczy	15 "	55
Kossel	18 "	104

In addition to these statistical facts we should take into consideration the personal opinions of writers. For example, Dr. A. Johnston, who took part in the discussion on diphtheria at the meeting of the British Medical Association, expressed the opinion, though he gave no statistics, that the antitoxin treatment did not affect either the mortality or the paralyses. Dr. N. T. Gamaleia, after reporting his cases,¹ states that while the remedy is effective against the diphtheria, it is less efficacious against polyneuritis. Escherich, also, after reporting fifty-one cases, states that antitoxin does not prevent paralysis, but does perhaps lighten it. Baginsky expresses the opinion, however, that if treatment be begun early it does prevent palsies, and reduces them to four or five per cent.

Taking the statistics as a whole, the percentage of palsies following diphtheria treated by antitoxin is somewhat lower than that which prevailed formerly. But there are some striking exceptions to this, and, apart from the figures, the general opinion is that the use of antitoxin does not lessen the frequency of these palsies. It is further stated in explanation of the occasional frequency of paralysis after antitoxin that a larger percentage of cases gets well, and hence there are more persons who are susceptible to the disease. The fact is assumed also that the severer the diphtheria the more likely one is to have a paralysis, and since more severe cases recover there are more patients especially susceptible to paralysis. This statement is made by Goodall, but it has not been the previous opinion of writers or observers generally and it is directly opposite to the statements made by Gower and also in Sachs' recent work on "Nervous Diseases of Children." One would think, on the other hand, that the proportion of cases that has recovered under antitoxin and that is susceptible to paralysis would be considerably lessened because a larger number of the younger children are saved, and these children are not so susceptible to palsy as the older ones. The percentage of diphtheritic palsies after use of antitoxin ought to be less, because the young are saved. Older children never did have a great death rate.

While it is shown by the figures so far collected that diphtheritic palsies are not increased by the use of antitoxin, the fact that they are not very much affected or not stopped shows that the antitoxin, however effective as a whole, is not given in sufficient doses to prevent the specific effect of the diphtheria on the nervous system. The absolute and final test of the specific character of the diphtheritic bacillus, according to Dr. Sydney Martin, is that it has the power to produce a poison which causes degeneration of the nerves and nerve cells. He asserts that injections of either the diphtheritic albumose or of the toxin obtained from the membrane will cause these degenerative changes when injected into animals. He asserts, furthermore, that the injection of the antitoxin does not cause these changes, and, third, he asserts that when animals have received injections of diphtheritic toxins and then of antitoxin, the nerves are not affected. The fact, therefore, that persons who suffer from diphtheria and who receive antitoxin injections

¹ "Ueber Diphtherie," etc., 1895.

¹ Vrach.

still develop post-diphtheritic paralysis shows at least that the antidotal action of antitoxin is not complete. It would not be fair to say anything more, and it may well be said that though this antidotal action is not complete, so far as the nerve centres are concerned, it is sufficient in a large number of cases to prevent serious destruction of the organism.

PULMONARY TUBERCULOSIS TREATED WITH MARAGLIANO SERUM.

By FRANCESCO CARLUCCI, M.D.,

NEW YORK.

THE serum therapy has given rise to many fears of a possibility of doing harm to the human organism, and nowadays there are theorists who would like to have it cast out from practice altogether. But these fears are exaggerated, because, by the clinical and experimental researches made by Zagari on healthy men and on patients in different stages of chronic nephritis, it has been demonstrated that the plain serum or the serum plus antitoxins in therapeutic doses is absolutely harmless to the kidneys. These observations have also been confirmed by Mya, Ranke, Seitz, and Kahaden. The serum therapy after its brilliant success in diphtheria has greatly widened the horizon to the clinician and pathologist.

Behring, Tizzoni, Nocard, Roux, Vaillard have applied the serum therapy in tetanus; Foà in pneumonia; Pleiffer and Ransom in cholera; Babes in hydrophobia; Zimmerman, Emmerich, and Roux in cancer; Marmorek in puerperal infection and scarlet fever with results more or less encouraging. After the failure of experiments with antitubercle serum made by Richet, Hericourt, and others, Maragliano succeeded in preparing a serum which has nothing in common with Koch's lymph. It is a transparent liquid of an amber-yellow color and of the density of the ordinary serum. We do not yet know the formula of its preparation; all we know is that the method of vaccination pursued by him is entirely different from that of others. He has used all the soluble toxic products of a virulent culture of human tuberculosis—that is to say, substances which are destroyed by heat, called protein, and substances resistant to heat, called toxin. The vaccine thus prepared is inoculated into dogs, asses, horses, in gradually increased doses till it reaches the highest proportion. From these animals the serum is drawn. We do not know the true action of the antitubercle serum any more than we know the action of the diphtheritic antitoxin. The serum neutralizes the toxic products (Maragliano), or exalts the natural means of defence (Bouchard), or acts by modifying the protoplasm of the cells. Whatever may be its action there is the essential fact that the serum neutralizes the action of the tuberculin. It is well known that an injection of three milligrams of tuberculin causes a reaction in a patient suffering from tuberculosis with no fever; now if the same patient be given first an injection of one cubic centimetre of serum and one of three milligrams of tuberculin afterward, the reaction is stopped. Evidently this fact shows that the Maragliano serum contains defensive substances.

Maragliano claims that in sixty per cent. of cases treated with antitubercle serum the results are good. When we think of the great death rate of tuberculosis, almost one-seventh of the human race succumbing, his statistics must be considered as very encouraging. I have tried the serum in five cases of pulmonary tuberculosis in which the examination of the sputum and the analysis of the urine were made by Dr. Giantureo, to whom I am greatly indebted.

CASE I.—N. N.—, woman, aged thirty-four, mar-

ried, has no children. Her mother died at the age of thirty years of pulmonary disease; her father, brother, and sister are alive and in good health. Two years ago she contracted a cold from which she never recovered. Physical examination, made on November 1, 1895, revealed a circumscribed chronic broncho-pneumonic focus with a small cavity and abundant râles at right apex. There were a few small râles at left apex. Temperature was 102° F., pulse 120, respiration 26 in the evening. The cough was so frequent that it caused pains all over the chest. There were night sweats, dyspepsia, and great debility. The expectoration was very abundant and of muco-purulent character, showing countless tubercle bacilli under the microscope. Her weight was one hundred and thirteen pounds. After ten injections of one cubic centimetre of serum made on alternate days the temperature fell to 101° F.; the pulse was 96 and respiration 22. After thirty-two injections the fever in the evening reached 99° F., pulse 84, and respiration 22. The cough became less frequent, so that the pain in the chest ceased entirely. The digestion was so improved that the patient could eat with appetite; thus she felt better physically and morally. On physical examination it was found that the râles had disappeared from the left apex and that there was no modification in the right. In the urine there was nothing noteworthy.

This amelioration brought about by the serum could not be obtained by a previous treatment with creosote during five months.

CASE II.—C. R.—, man, aged twenty-five, fruit pedler. His mother died of tuberculosis, his father is alive. He had always been well till last October, when he became ill with a pleurisy on the left side. On November 5th he was admitted to the Italian Hospital in very bad condition. His temperature was 102° F., pulse 130, and respiration 34. Cough was frequent and expectoration abundant. Physical examination showed a pleurisy with a small effusion on the base of left lung and a broncho-pneumonic focus with a cavity on the apex of the same side, with exaggerated breathing on the right side. The sputum showed numerous bacilli with some microbic association. After fifty cubic centimetres of serum had been injected the temperature became normal in the morning, but toward evening it reached 100° F.; pulse 102, respiration 22. The condition of the patient was greatly improved, the cough was diminished, the expectoration was not so abundant and showed less bacilli. Night sweats were diminished also. His weight was one hundred and twenty pounds, he having gained two pounds. The physical examination of the lungs improved somewhat, showing the disappearance of the effusion and a diminution of the râles. When the patient left the hospital his temperature was 99° F., pulse 88, respiration 22, and he felt so strong as to undertake a trip to Italy.

CASE III.—G. W.—, man, aged twenty-four, married, has one child. His father and mother are alive and in good health; an uncle died of tuberculosis. He had always been well up to three years ago, when he had an hæmoptysis which lasted three days. After that he began to lose flesh. On November 18, 1895, he was admitted to the hospital. The patient appeared very much emaciated and pale; his weight was 116 pounds. His temperature was 101° F., pulse 120, respiration 20. He coughed at long intervals, raising a scanty white expectoration. The physical examination of the lungs revealed a circumscribed broncho-pneumonia at the right apex. The sputum showed numerous Koch bacilli under the microscope. After ten injections of one cubic centimetre of serum the temperature was lowered to 99° F.; pulse 98, respiration 18. After other thirty-four injections the temperature became normal,

pulse 84, respiration 18. He coughed only a few times daily; the night sweats ceased completely; his appetite improved and his weight increased three pounds, so that, feeling himself comparatively strong he left the hospital. The expectoration ceased entirely, so it was impossible to obtain any quantity for examination. The râles disappeared from the right apex.

CASE IV.—K. C.—, woman, aged thirty-five, has been married twice. She has had seven children, four being alive. Her father died of tuberculosis and a brother of pneumonia; her mother is alive and well. On February 18, 1895, she had an attack of bronchitis; her physician treated her with creosote and cod-liver oil, but not having improved with this treatment she applied for the serum on November 30, 1895. The physical examination of the chest revealed a circumscribed broncho-pneumonia at the right apex and only a few small râles on the left. Nothing of any importance was found in examining the other organs. Her weight was one hundred and twelve pounds. On December 6, 1895, she was given the first injection of one cubic centimetre of serum. Her temperature was 100° F., pulse 116, respiration 24. After forty injections of one cubic centimetre each, the maximum temperature recorded in the evening was 99° F., pulse 88, respiration 22. The sputum showed scarcely any bacilli, which before treatment were quite numerous. Râles on the left apex disappeared and respiration on the same side became normal, while on the right side only few râles were heard compared with what were manifest before. Her weight increased two pounds. She felt better than she ever had before.

CASE V.—M. S.—, man, forty-four years old, merchant. There was nothing noteworthy in the history of his family. Four months before he had begun to cough and to lose appetite and strength. The examination of the lungs revealed small râles at the left apex. The temperature was normal, pulse 100, and respiration 24; his weight 203 pounds. The sputum showed the presence of Koch bacilli. The patient received thirty injections of one cubic centimetre of serum. The temperature was always normal; the pulse became stronger, 85, and the respiration diminished to 22. His weight increased to two hundred and fifteen pounds. Fewer bacilli were found in the sputum, which became very scanty. Only a few small râles were heard at the left apex.

In the first three cases I noticed that the temperature after twenty cubic centimetres of serum had been injected went up to 103° F., while it had always been lowered by the first five or ten injections. This rising of temperature ceased, however, by discontinuing the injections for a week. In all these cases the urine never showed either albumin or hæmoglobin or peptone.

In conclusion it can be said that

- (a) The serum is innocuous.
- (b) The serum causes the drying up of broncho-pneumonic foci.
- (c) The serum improves the appetite and increases the weight, so that the general return of physical force is felt.
- (d) The effect of the serum is gradual.

If for a moment we make a comparison between the results of the antitubercle serum therapy and those of the ordinary methods of treatment (creosote, guaiacol, iodoform, etc.), I think the serum must nowadays be considered as the best curative means at our disposal.

In Italy more than three hundred cases have been treated with the serum with very satisfactory results. The same results have been obtained by Gerhard in Berlin and by Babes in Paris.

Dr. Vidal, after having tried the Maragliano serum, says that he is perfectly satisfied with its action. It must be maintained that because of the harmlessness

of the serum we are justified in attempting to help the consumptive by this inoffensive treatment, which certainly is destined to give in the near future results which the most rational pharmaceutical treatment has never given.¹

233 EAST FOURTEENTH STREET.

Progress of Medical Science.

Some New Observations on Trichinosis.—The views of Leuckart on trichinosis have been generally accepted by the profession. It will be remembered that according to him the young trichinæ are born in the intestinal tract and later on pierce the walls of the bowel before migrating to the muscles. Dr. Askanazy has recently pointed out that nobody has ever actually observed the migration of the embryonic trichinæ through the walls of the intestines. Nor has any satisfactory explanation ever been offered for the curious circumstance that the trichinæ find their final lodgment only in the muscles. Dr. Askanazy has lately completed an experimental study of trichinosis, the results of which are published in the *Deutsche Medizinische Zeitung*, February 24, 1896. The animals experimented on were rabbits. He claims that the adult female trichinæ find their way into the mucous membrane of the intestine and there deposit their embryos. The lymph channels are specially selected for the deposition of the embryos. The young trichinæ are then carried to distant parts through the agency of the fluid circulating in the lymphatic vessels. This would explain why several days after feeding trichinæ to an animal the males so largely preponderate over the females within the intestinal tract. It would also explain why it is sometimes impossible to discover trichinæ at all within the lumen of the bowel. The practical observation has also been made by the author that aperients are quite useless in the later stages of trichinosis. The author also regards the presence of trichinæ in various organs in the light of embolic infarction rather than as due to active migration. He is unable to assign any particular reason for the special predilection shown by the young trichinæ for striped muscle.

Typhoid Fever in Children.—Dr. John Lovett Morse (*Boston Medical and Surgical Journal*), in an interesting and instructive article on typhoid fever in children, offers the following conclusions: "Typhoid is a common disease in childhood but rare under two years. It occurs about as frequently in children between five and ten as in those between ten and fifteen. The mortality, in cases under fifteen, is about six per cent., or half that in adults. The rate of mortality increases directly with the age. The course is shorter and less severe than in adults, this, as well as the low mortality, being due to the slight intensity of the intestinal lesions. The severity increases directly with the age. The onset is acute in about one-third of the cases in the second five years and in about one-fifth of those in the third five years. Nose-bleed occurs in about fifty per cent. of all cases and is often severe. The average duration of the fever is a little less than three weeks, being somewhat shorter in younger than in older children. The proportion of cases in which the duration is not more than ten days is twice as great in children under ten as in those over ten. The temperature curve is less typical than in adults. The remittent second stage is absent in more than fifty per cent. of the cases under ten and in forty per cent. of those between ten and fifteen. Relapses are nearly as frequent in children as in adults and follow the same

¹ See *Nouveau Montpellier Médical*, February 3, 1896, "À propos du serum antituberculeux du Professeur Maragliano."

course. The tongue is rarely as dry as in adults. Vomiting is a common initial symptom and is not very infrequent during the course of the disease. It is not an unfavorable symptom. Constipation is more common than diarrhœa, especially in younger children. Distention is present in from fifty to seventy per cent. of all cases, and is more common in younger children. It is not infrequently extreme. Tenderness is present in about half of the cases, but is rarely very marked. Hemorrhage is very rare under ten years and much less common above that age than in adult life. It is fatal in about half of the cases. Perforation is extremely uncommon. Rose spots are present in from sixty per cent. to seventy per cent. of all cases. The spleen can be demonstrated clinically to be enlarged in from eighty per cent. to ninety per cent. of all cases. This enlargement is usually moderate but may be extreme, more commonly in young children. Capillary bronchitis occurs in about forty per cent. of all cases. In some cases it may mask the abdominal symptoms, especially in younger children. Other pulmonary complications are rare. Headache is complained of in about seventy-five per cent. of all cases, but is rarely severe. Marked nervous symptoms occur in at least twenty-five per cent. and are equally common at all ages. The condition is one of stupor in from fifteen per cent. to twenty-five per cent., and of delirium in the remainder. The delirium is more commonly active. Crying out at night is common, especially in young children. Meningeal symptoms are not infrequent and are more common in young subjects. Neuritis occurs, probably more often than is supposed. Albuminuria is common and occurs with equal frequency at all ages. Serious renal complications are rare, especially in young children.

Hæmostatics in Hæmophilics.—Dr. H. C. Howard, of Champaign, Ill. (*American Jour. of Surg. and Gyn.*), has for twenty years used hypodermic injection of a saturated solution of tannic acid around the seat of bleeding. Dissolve the acid by aid of heat. Make from three to six injections around the seat of the injury, using a saturated solution as hot as can be stood. Also inject hypodermically one-twentieth of a grain of strychnine and repeat every two hours if needed. Strychnine by its influence upon the vasomotor nerves usually checks bleeding in a short time, but when the amount of blood lost is considerable it is best to adopt the above method of local treatment.

Umbilical Hernia in Infants.—Dr. Cahier has studied this subject and reaches the following conclusions: 1. In the children of either the rich or poor the radical cure of umbilical hernia must be tried up to the age of eighteen months or two years, unless there be certain exceptional contraindications. 2. In these young patients the use of the conical pad and the elastic spring are to be avoided. A hemispherical hard-rubber pad supported on a metal plate and held in place by a bandage is the best appliance. The apparatus should be changed every eight or ten days. 3. In children two to seven years of age belonging to well-to-do families, who are carefully looked after, an attempt may still be made to cure the hernia by bandage. 4. Children of the same age, whose parents are poor and consequently unable to give the necessary care to the child, or if they are negligent or ignorant, should not be subjected to this treatment if there is any tendency for the hernia to increase or to give trouble. 5. The umbilical hernias which persist after the seventh year, in spite of the careful use of the bandage, may be treated by other measures. The author favors surgical interference under the following circumstances: 1. Umbilical hernias of the newborn if strangulation occurs or if persistent gastro-intestinal troubles are

induced which seem to be dependent upon the hernia. 2. The hernias in children of from two to seven years present analogous indications. 3. Children of this age belonging to poor families, who do not receive proper attention, if at the end of a year or eighteen months the hernia is still of the same size. 4. Hernias that persist after the seventh year, that are rebellious to treatment, and tend to increase in size. 5. If the skin covering the hernia is inflamed or ulcerated. 6. If the hernia interferes with the occupation that the person has selected. 7. Umbilical hernias with a large ring. 8. Those that are subject to strangulation or inflammatory accidents. 9. Those that cause pain and gastro-intestinal disorders, and consequently interfere with the development of the child.—*Revue de Chirurgie*.

Practical Disinfection of Rooms.—The frequency with which second and third cases of scarlet fever appear in houses that have been disinfected by the inspectors of sanitary authorities, says *The Lancet*, causes grave doubts as to the efficiency of the procedure usually adopted, despite its official sanction. Stripping the walls, lime washing walls and ceilings, and scrubbing woodwork and floor boards with soap and water are indeed effectual enough, and to these when thoroughly done we are disposed to ascribe any successful results rather than to the more technical process of so-called disinfection by sulphur fumes, which is little better than a superstitious rite or incantation shorn of the religious character it had in the mind of Ulysses when he "fumigated" the halls desecrated by the massacre of his wife's suitors after removing the corpses and washing away the blood with a promptness that precluded all thought of other than moral pollution. But in the light of bacteriological experiments dry sulphurous acid fumes, whether generated by burning sulphur or carbonic sulphide, or, as has of late become the fashion, by opening cylinders of the compressed gas, are for all practical purposes useless. The gas would act as a fairly powerful germicide on articles or fabrics previously saturated with water, but its bleaching action precludes its employment in this way with colored materials, carpets, or curtains, and it is as what is called an "aerial disinfectant" that it holds its ground in popular esteem. But aerial disinfection is an absurdity; no one wants to purify the foul air, which is easily enough removed by simple ventilation. In disinfecting a room the true aim is to kill the germs contained in the dust on ledges or in the crevices between the boards, or adhering to the walls and other surfaces, and the dry gas is powerless for this, which is best attained by a sublimate solution of the strength of 1 part in 1,000, or by lime (not white) washing, provided the lime be fresh burnt and caustic; the carbonate or chalk used in whitewashing under the name of whitening, and into which lime is converted by long exposure to the air, being inert. The series of experiments on the infection and disinfection by various means of wall papers, distempers, and other wall surfaces conducted by Dr. Cronberg, under the direction of the late Professor Uffelmann at Rostock, showed that subsequent scrapings were invariably and almost instantaneously sterilized by washing or spraying with the sublimate solution, and equally so by lime wash after the lapse of twelve to twenty-four hours. The danger of corrosive sublimate is, we believe, exaggerated, for the smallest fatal dose for an adult being probably three to five grains—equal to at least a quarter of a pint of the solution—accidental poisoning with the solution is practically not probable, and as a further safeguard it might be colored with indigo or "laundry blue." Carbolic acid, which is sold without restraint and is in universal use, is more dangerous on that account, and is, indeed, fre-

quently employed with suicidal intent and with fatal effects. In France, Germany, and Italy sublimate has nearly superseded all other disinfectants and its neglect in this country is inexplicable. As to carpets, curtains, bedding, and clothing, all that is capable of being washed should be plunged in a copper of boiling water for a quarter of an hour and such articles as would be spoiled by this treatment should be disinfected by steam.

A New Styptic.—Roswell Park (*Medical News*) finds a spray of five-per-cent. solution of antipyrin made up in sterilized water a useful styptic in surgical operations, especially in parenchymatous oozing. He considers a combination of antipyrin and tannic acid still more useful, as it precipitates a thick, gummy, cohesive substance which is an ideal styptic for certain purposes. An alcoholic solution of tannic acid may also be taken and antipyrin added until it forms a precipitate of the required consistency. This is useful in hemorrhage from bone, as in operations upon the cranium. The only difficulty connected with it is the difficulty of detaching it. Sometimes it is necessary to wait for the formation of granulations and separation by natural methods.

Pseudo-Puerperal Infection from Constipation.—Dr. L. Dulrisay mentions (*American Medico-Surgical Bulletin*) the fact that constipation after confinement may give rise to many of the symptoms of puerperal infection. He cites a case in which there was no movement for four days. The temperature reached 103° F., pulse 120, tongue coated, breath fetid, and abdomen swollen and tender. The symptoms all disappeared after active purgation.

The Passing of Hypnotism.—Hypnotism as a therapeutic agent is now having its day in regular medicine, but it is a day that is probably well past its meridian, says an editorial writer in the *Journal of the American Medical Association*. The belief that it has its dangers and that these overbalance its possible benefits has grown within the past few years, and the number of regular physicians who use it in their practice is probably very markedly on the decrease. It is legitimate to utilize pathologic conditions and even to produce them in therapeutics, but it must be demonstrated as of utility on reasonable *a priori* grounds, or, at least, have the best of clinical and experimental evidence in its favor to make it expedient or justifiable. When, with a better knowledge or theory of the condition the *a priori* deductions tend to its disfavor as a healing agency, only the most decided clinical proofs of its value, applying not only to immediate but also to remote results, should be required before its use in the treatment of disease is countenanced to any extent. The revival within the past sixteen years of interest in hypnotism, the claims of the Nancy school, and published accounts of the experiences and practice of numerous physicians and scientific men of repute, such as Forel, Voisin, Benswanger, Bramwell, and others, have given it a certain status in legitimate therapeutics considerably beyond what it possessed in its former period of cultivation some fifty years ago. It is probably not known to the general medical public of to-day, or if known is forgotten, that at that time it had its popular pseudo-scientific standing and was investigated by men of science, who came to very much the same conclusions as those of the present day. This fact has been well shown by Dr. Kiernan, who states that the earlier alienists of this country recognized the dangers of hypnotism, its psychologic basis, and the element of morbidity that is required to predispose to susceptibility. The outcome of the whole at that time was to relegate it back among the pathologic curiosities of little practical value, and it slumbered, in a

medical point of view, for over thirty years. It seems probable that we are to see history repeat itself, and that before many years the medical profession will drop hypnotism as a therapeutic agent: at least, that will be the general if not the universal rule, and its use will be mostly confined, as it was during the years between 1848 and 1880, to the irregulars outside of the recognized schools of medicine. That is its tendency at the present time, and while some unquestionably able men are still experimenting with it, a too great credulity as to its value and powers has seriously injured some high scientific reputations—that of Luys, of Paris, for example, among others. We need not, says the *Journal*, particularize here on what may be rightly called the thoroughly disreputable therapeutics of hypnotism as applied by certain prominent German physicians. The dangers of hypnotism are already indicated when we consider its close relationship to hysteria and to hysterical conditions, which has been shown by Charcot, Gilles de la Tourette, and others in France, Germany, and elsewhere. Of all pathologic conditions hysteria would seem to be one of the least likely to be therapeutically useful, and the utilizing of hysteroid anæsthesias and other disturbances of consciousness, going so far, even, as to the production of what may perhaps be properly called epileptoid conditions of double consciousness and amnesia, without regard to the after-effects of such disordered cortical functioning, is not a procedure that ought, it would seem, to be countenanced as a legitimate method of treatment of any condition; a condition, moreover, in which the will is in abeyance is not a normal one and its tendency must be to weaken the inhibitory power of the brain and change its functions, possibly even to the extent, in some cases, of producing serious mental disorder. As Hack Tuke mentioned, some thirty years ago, hypnotic conditions have in a fashion something of the character of an induced temporary insanity, and their too frequent repetition may make the derangement a permanent one. Such has undoubtedly been the case in not a few instances, to say nothing of the aggravations of hysteria and even the production of epilepsy in some cases. The dangers of hypnotism are real, and the fact that the majority of the victims escape the worst of them, does not in any way excuse the reckless experimentation that is sometimes carried on for ostensible therapeutic ends. If the major hypnotism, or that which commonly goes under the name and is attended with marked disturbances of consciousness, has even any utility in treatment, it must be a very limited one and the chances of its doing mischief greatly outweigh its advantages. It may be asserted that the interest in the subject has been to the advantage of the profession, by calling attention to the therapeutic value of suggestion, and, to a certain extent, this claim may be allowed. It has not, however, increased our practical knowledge in this direction; it has only led to a possible wider recognition by the regular profession of the advantages of suggestion. The legitimate use of suggestion is, however, quite as different from hypnotism, as the latter is generally understood and practised, as it is from its illegitimate use, which leads directly to quackery.

The Fœtus as a Patient.—The risks to which the fœtus is subjected in parturition have been engaging the attention of Dr. Demelin. In referring to his studies editorially, the *New York Medical Journal* says that it may be readily understood that the child is often endangered during labor, for a large number of diseases affecting the mother lead to jeopardy of the fœtus—such as the various infectious diseases, febrile or not; such as variola, syphilis, etc., in course of evolution; certain visceral diseases, such as the affections of the heart in the asystolic stage, renal lesions with uri-

nary toxæmia, etc.—in fact, all grave conditions which begin ordinarily before labor, and, moreover, are capable of provoking premature birth. The size of the child should also be taken into consideration, for if it is very small it offers a feeble resistance to injury. Protracted labor, premature rupture of the membranes, premature detachment of the placenta with the hemorrhage it causes, compression of the cord and especially its prolapse, are the principal causes of danger to the child, and they should always be considered as possible or probable. All this, however, says the writer, is mere supposition, and more convincing proofs of actual danger to the child are required. Two kinds of symptoms lead us to infer that the child is in peril:

1. Modifications of the fetal heart sounds.
2. Changes in the amniotic liquid.

With regard to the first symptom, says Dr. Demelin, in a normal condition the fetal heart beats regularly and rapidly in the interval of the uterine contractions; the pulsations are from 120 to 160, sometimes less, but always more than a hundred if the fetus is healthy. The beatings are powerful, distinctly perceptible, with an intensity which renders them unmistakable, and there is no synchronous souffle. But a uterine contraction supervenes, and the cardiac rhythm becomes modified, especially if the period of expulsion has begun and if the membranes of the ovum are already ruptured. On auscultation when the uterine wall hardens, we find that the fetal heart beats, after a very transitory acceleration, diminish in intensity and in rapidity. At the height of the pain they become very slow and occasionally they cannot be perceived, but when the contraction begins to subside they gradually regain their force and rapidity. Slowing of the heart's action, says Dr. Demelin, should not cause any uneasiness if it is observed during a contraction, but the case is quite different if the cardiac rhythm changes during an interval between the contractions; then it may be said that the child is in peril if the heart beats become blowing, if they fall below 100 a minute, if they are irregular or very feeble, and, finally, if they become extremely rapid after having been previously slackened, for instance, more than 160 a minute. When the heart beats fall below 20 a minute, death is near. It is not always easy to practise auscultation, says the author, on account of the movements of the patient, and if the uterine contractions follow each other without intermission it is impossible to obtain stethoscopic information. Besides, the child may really be in danger, although the rhythm of the heart beats appears normal during the intervals. This contingency, which, without doubt, says the author, is exceptional, is nevertheless proved by the sequence of events and particularly by the modifications presented by the amniotic liquid. With regard to changes in this liquid, says Dr. Demelin, the alteration of the cardiac rhythm gives information as well before as after the rupture of the membranes, and it is in this that the importance of this symptom lies. The amniotic liquid which is discharged at the moment of the artificial or spontaneous rupture of the membranes should be transparent, yellowish in color, with a peculiar odor, but not fetid. When these characteristics are retained the child is not in danger. If the liquid, however, becomes of a greenish color, more or less dark, we should be alarmed, and if it becomes thick, like a thick soup, there is still greater reason for alarm, especially when there is a peculiar fetid odor noticed. At the very time when the amniotic liquid is infected the heart beats may appear to be normal, and the situation is all the more alarming because the danger is insidious, for it is not perceived until a discharge of amniotic liquid occurs. Often it is then too late to save the child; it may be extracted living, but death nearly always follows from infection. When the fetus presents by the breech a green color

of the amniotic liquid, due to the meconium, is of no grave significance. The uterine contractions then compress the abdomen and expel the meconium, which is found in similar circumstances in rather large clots instead of being liquid. In other presentations the presence of meconium in the amniotic liquid is always an alarming sign as regards the child; if the liquid is very thin the danger is greater than when there are masses of meconium, and the maximum of gravity is reached when there is much fœtor and when at the same time there are profound modifications in the rhythm of the heart beat. On the whole, says the author, a green color of the amniotic liquid always indicates a serious danger for the child, and perhaps it has a greater prognostic importance than abnormal action of the fetal heart. With regard to the treatment in such cases, says Dr. Demelin, nothing is simpler, theoretically at least. Labor must be terminated as soon as possible, and it is important to work rapidly, but without violence or precipitation, for although the child may be able to resist asphyxia, it is very susceptible to traumatism, and resuscitation is more easily and surely accomplished after a slow operation than after a rapid and violent intervention.

Syphilis of the Placenta.—Dr. Schwab (*La Presse Médicale*, December 14, 1895) has made a histological study of placenta syphilis, from which he concludes that lesions are to be observed in these cases, which belong with the recognized manifestations of the disease. They are characterized especially by signs of endo-periarteritis, so well marked that they may be looked upon as specific changes. The author thinks one can henceforth describe a syphilitic placenta just as we speak of a syphilitic liver.

Fundus Height during Labor.—Fothergill (*Edinburgh Medical Journal*) has taken measurements during various stages of labor. The fundus rises three-tenths of an inch before labor ends, while the measurement from the fundus to the pubes lessens one inch before birth. The length of the parturient canal is not shortened before delivery. The womb grows narrow as the child passes through the uterus into the vagina. As labor advances the uterus contracts antero-posteriorly. The fundus does not sink before the birth of the head.

Poisoning with Nitric Acid.—Dr. Moser has reported the post-mortem findings in a case of poisoning with nitric acid (*Brooklyn Medical Journal*). The mucous membrane of the mouth was yellow, that of the œsophagus softened. In the latter the longitudinal folds were abnormally prominent, and covered throughout their entire length by yellowish streaks. The mucous membrane between these folds was a little reddened and soft, but not stained. The mucous membrane of the stomach, from its cardiac to its pyloric extremity, was converted into a thick, greenish-black slough. The mucosa was thrown into prominent folds. There was no perforation. The mucosa of the duodenum was softened and yellow. The small intestine was but slightly affected, and contained a black fluid. The intestinal discharges were of a bloody character. The heart, the blood, and the spleen presented no change. The kidneys and liver showed parenchymatous alterations. The pancreas was the seat of parenchymatous inflammation with punctate hemorrhages.

Diphtheria of the Skin.—We are told by the Berlin correspondent of *The Lancet* that Dr. Flesch, of Frankfurt, has observed this case: A girl, aged two and one-half years, was scalded with boiling water on August 3d, nearly the whole left side from the lips to the umbilicus being involved. On the places where the clothes had retained the hot water the effect was very severe, while it was superficial on the face and neck. The whole of the injured surface was covered

with two-per-cent. salicyl vaseline and cotton wool, the dressing being changed daily. The child on the first evening had a temperature of 39.6° C., but felt quite well the next day. On the seventh day the superficial scalds of the neck and face were covered with fresh epidermis, so that the dressing was no longer necessary there, and the mother, overjoyed at this improvement, kissed the girl's neck just on the limit where the deep wound was beginning to granulate. On the following day the mother suddenly complained of pains in the throat, and in the evening an obviously diphtheritic inflammation of the tonsils was visible. She and the child's aunt, who was seized with the same disease, were therefore isolated, and the child's father, who felt ill the following day, had apparently a slight sore throat, the nature of which was very probably diphtheritic. Both ladies were treated with injections of Behring's antitoxin and subsequently developed hemorrhagic nephritis, but quickly recovered. On August 13th the spot where the child had been kissed showed a very remarkable alteration. The skin was covered by a gray mass and was much swollen, the œdema extending as far as the eye, while the edge of the spot was irritated and somewhat elevated. The child was, therefore, treated with Behring's antitoxin, and on bacteriological examination of the gray mass Dr. Benario found an abundance of Loeffler's bacilli and cultivated them on agar. On the third day the gray mass disappeared, together with the œdema, but was replaced by an ulceration, which healed after a short time. Some time afterward a slight paresis of the palate appeared, but there was no other complication, the throat of the child being unaffected. Professor Flesch states that diphtheria of the skin usually occurs only in the neighborhood of tracheotomy wounds, and is very rarely found in other parts. As the diphtheria attacked the new epidermis but spared the granulations, he concludes that the moist granulations hindered the disease from spreading over the whole surface of the body, but that newly formed epidermis is favorable to the growth of Loeffler's bacilli.

Double Penis.—At a recent meeting of the Clinical Society of London, a report of which appears in *The Lancet*, Mr. John H. Morgan showed an infant eighteen months old who presented the following abnormalities of the external genitals. On each side there was a large and well-formed mass of scrotal tissue containing well-formed testes, with spermatic cord and vas deferens. These were separated from each other at their upper extremity by two well-formed penes, which measured about three-fourths of an inch in length, the left being rather longer than the right. In each the frænum was absent, and the corona was but slightly marked. There was no urinary meatus in either. Each was attached to the ramus on either side, the pubic rami and symphysis being apparently normal. Below the root of these two organs was another prominent mass of tissue about three-fourths of an inch in length, consisting of a pouch of skin and subcutaneous tissue, in the centre of which was a firm and more fibrous body which was attached immediately below the two penes, lying midway between the two scrotal prominences, there being a deep sulcus on each side between it and these. Posteriorly to this finger-like process was a mass of skin and subcutaneous tissue covered by epithelium resembling that of skin except upon its posterior surface, where it was more like mucous membrane. This projected forward about half an inch and looked like a small mamma, on which was a prominent bluish nipple. The left part of it was a small pedunculated body which stuck out like a small pea and was attached to the finger-like body. Below this, lying in the middle of the perineum and in front of the anus, was a prominent mass of mucous mem-

brane measuring about one and one-fourth inches from before backward, and three and three-fourths inches from side to side. This was very red and vascular, and protruded when the child cried. Along its right attachment was a slit about half an inch long, which admitted a probe into a long narrow cavity passing vertically upward for about two inches, in which the probe could not be moved laterally. This was evidently the mucous membrane of the bladder, as the urine drained from this surface when the child was at rest, and when it cried was driven in jets from the orifices of the ureters, which could then be seen. Behind this protruding mucous membrane lay the anus, which easily admitted the little finger, but no abnormality could be detected in the rectum. The child presented no other abnormality except that at the upper part of the lobule of each ear there was a small fibrous prominence. Nothing abnormal could be discovered on auscultation of the heart, but the limbs became much cyanosed when it cried.

The Absorption and Elimination of Lime Salts.

—Some years ago Rudel published a study wherein he showed that when rhachitic infants are fed in the same manner as healthy ones their urine contains the same, or very nearly the same, quantity of calcium, and that in the two classes the elimination of lime salts increases equally under the administration of pharmaceutical preparations of lime. From this, says the *American Journal of the Medical Sciences*, Rudel concluded that the absorption of lime salts from the intestine was accomplished in the same way in both rhachitic and non-rhachitic subjects, and that rhachitis should not be attributed to an insufficient absorption of the lime salts of the food. In another series of experiments Rudel showed that the administration of acids capable of dissolving lime salts (*e.g.*, HCl) increased the elimination and consequently the absorption of lime salts, and, *per contra*, that elimination and absorption are diminished by the administration of substances which possess the property of precipitating the lime salts (phosphate of sodium): and, finally, that absorption of lime salts is increased when the intestinal peristalsis is retarded (opium), and diminished when the contractions are increased (diarrhœa). Finally, Rudel showed that the proportion of lime salts is the same in the fæces of rhachitics and non-rhachitics when the two are submitted to the same diet or the same medication. This work has been recently reinvestigated by Rey (*Deutsche med. Wochenschrift*, 1895, No. 35, p. 569), who confirms the conclusions already drawn by Rudel. In the first series of experiments he shows that there exists a direct connection between the proportion of lime salts in the urine and those in the fæces, so that a knowledge of the quantity of lime salts in the urine gives evidence of the absorption and elimination of these salts by the organism. In another series of experiments made with rhachitics he demonstrated that the administration of a lime salt (acid acetate of lime) is followed for several days by an increase in the proportion of calcium in the urine. In a third series of experiments the author studied the influence of phosphorated cod-liver oil, simple cod-liver oil, and phosphorus alone, upon the absorption and elimination of lime salts in rhachitics. The researches based upon analyses of the urine showed that the phosphorated oil decidedly increases both absorption and elimination, even more notably than the plain oil. On the other hand, phosphorus alone seemed not to exercise any influence upon either process.

Creosote in Lupus.—Gérénine recommends the beechwood product, pure in compresses, or a ten to thirty per cent. solution in oil or glycerin. The treatment is slow, but produces a minimum of scarring.—*Semaine Médicale*, 1895.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, April 11, 1896.

ASEPTIC SURGERY IN GERMANY.

THE student who was asked to give the mathematical definition of a straight line, and who merely answered that any fool could draw one, was in the same position as is the average medical man when questioned on asepsis as he may understand it. The answer is equally direct and expressive when the real meaning of absolute cleanliness of instruments, wound dressings, and operator are clearly appreciated. The principles are acknowledged, but the details of their evolution are mostly at fault. In commenting on the latter point an admirable text is given in an article by Mr. Gabriel W. S. Farmer in the *London Medical Magazine* for March, on "Aseptic Surgery in Germany." We are safe in premising that aseptic surgery is carried to greater perfection in that country, except perhaps with those who follow German methods here, than anywhere else in the world. According to Mr. Farmer's own statements, in London surgeons are far from being careful, proving that Lister, their own townsman, is too near to affect them by his example and is thus without the usual honor, in a scriptural sense at least, in his own home.

"It is no rare thing," says he, "to see surgeons in England operating in old coats put aside for the purpose, comparable to the old coats which we keep in the dissecting-room. In England I have seen surgeons using nail brushes which lie about anywhere, which are used for washing away pus or even faces from one's hands, which are supposed to render one's nails and fingers aseptic, and which are rarely if ever sterilized. . . . One sees blankets brought straight from the bed of the patient to the operating-table, remaining there throughout the operation."

As an offset to these surgical misdemeanors the operator dips his hands into a solution of carbolic acid or of bichloride of mercury, washes out the wound with some chemical, and applies non-sterile but fancy dressings. All this in the very home of the prophet!

It is very properly admitted that we have made great progress since Lister first enunciated his principles, a fact due almost entirely to the patient and exhaustive studies of the German bacteriologists, and quite naturally we look to them as the enunciators of the advanced doctrine of asepsis. It is with such a view that we are impelled to give the impressions of the

aforementioned writer on some of the essentials of proper wound treatment. He makes three divisions of his subject: 1, the preparation of the patient; 2, the preparation of the surgeon and assistants; 3, the operation itself.

Everything turns upon absolute cleanliness before and during the operation rather than afterward. It is asepsis pure and simple against antiseptics always imperfect and always difficult. The patient is usually scrubbed thoroughly with soap and water just previous to the operation, and also the day before if possible. Each time he is either wrapped in sterilized sheets or sterilized pajamas are used. All hair in the neighborhood of the field of operation is shaven, and the prospective wound area is again thoroughly washed with soap, water, and sterilized nail brush while the patient is on the operating-table. The parts are dried with sterilized towels or gauze, and finally washed with alcohol, ether, and sublimate solution, 1 to 1,000. Next sterilized towels are spread around the body, leaving only the field of operation exposed.

The preparations for the operator are equally thorough and elaborate. The coats are laid aside in a room apart from the patient, where a preliminary washing of hands and arms, and cutting and cleansing of nails take place. The surgeon and assistants then put on long, freshly sterilized linen gowns with short sleeves. The final washing of hands and forearms takes place in the operating-room, first with soap, water, and nail brush; then with eighty-per-cent. alcohol, and in some instances with ether besides; and lastly with a sublimate solution, 1 to 2,000, the hands being immersed for a minute or more in the latter. The nail brushes and nail cleansers are kept in separate dishes immersed in sublimate solution, 1 to 1,000, and are boiled after each operation.

As to the operation itself, all instruments are boiled for five minutes in a dilute solution of soda, and after immersion in cold sterilized water for cooling purposes are placed upon a sterilized-gauze tray. Sterilized gauze is used instead of sponges. From the beginning to the end of the operation no antiseptic touches the wound. The dressings are simply composed of dried sterilized gauze and are kept in place by sterilized bandages. In a considerable number of cases the dressing is iodoform gauze covered with collodion. Drainage is mainly carried on by strips of sterilized iodoform gauze, rubber tubes being rarely used. Kocher uses sterilized glass tubes. Infected wounds are packed and when healthy granulations appear are united by secondary suture, a method specially advocated by v. Bergmann.

In reference to wound irrigation the following significant statement is made: "The germ-killing influence of antiseptic wound irrigation does not rest upon experimental evidence for its truth." As to the possibility of destroying pus germs by such means grave doubt exists; indeed, it is boldly claimed and with good reason that aside from lessening the number of pathogenic bacteria, no other influence is noted; in fact, that surgeons who do not use irrigation have equally good results with those who do. Here comes

the real difference between asepsis and antiseptis, the former being the scientific and the latter the empiric method of wound treatment. Asepsis prevents infection, but antiseptis cannot effectually kill all the morbid germs in a wound already infected.

While giving the technique of the German methods, we are pleased to state that American surgeons are in all essential respects up to date, are firm endorsers of the German practice, and are staunch believers in the principles of absolute cleanliness, thus preventing the possibility of mischief rather than making vain attempts to remedy it after inviting it.

THE MECHANICAL TREATMENT OF HEART DISEASE.

THE employment of systematic and carefully regulated muscular exercise in the treatment of cardiac disorders is of comparatively recent origin. While the method may never become universally applicable in the routine of general practice, there is, nevertheless, enough in it to merit serious attention.

Dr. Robert Saundby, of Birmingham, England, has published in the *British Medical Journal*, No. 1818, 1895, some remarks on this system of treatment under the title of the "Schott [or Nauheim] Treatment of Heart Disease." Saundby's remarks bear impartial testimony to the value of this method of practical therapy. The author tells us that the beneficial effects of Nauheim baths in the treatment of chronic cardiac disease were first proclaimed by the late Professor Bencke, about 1872, before which time there existed an unfounded dread of employing them in these cases. A few years afterward his teaching was reinforced by monographs from the pens of Drs. August and Theodor Schott, and the Nauheim bath treatment for heart disease gained considerable repute in Germany. The success obtained by the Zander movement cure induced Dr. A. Schott to devise a system of mild gymnastics or drill for the treatment of neurasthenic and hysterical patients, of whom a considerable number come annually to Nauheim. Some of these patients had rapid weak hearts, and it was discovered with some surprise that the exercises, instead of quickening the heart's action, slowed and steadied it; further experience showed them that this result followed also in organic disease of the heart, so that a method originally devised for steadying and strengthening the nervous system proved to be a valuable adjunct to the bath treatment of cardiac disease.

As to the method or system followed at Nauheim, we are informed that it consists of medicinal baths and muscular exercises, supplemented if necessary by graduated mountain climbing.

Dr. Saundby is disposed to agree with Schott in the opinion that the system is of special value in all cases of chronic heart disease except those in which there is advanced degeneration of the myocardium, or aneurism of the heart or great vessels, or advanced arteriosclerosis. It has proved of great service in all forms of valvular disease, in congenital cardiac defects, in simple dilated hearts without valvular disease, in the

functional cardiac debility of anæmia, however induced, in nervous irritable hearts, in simple tachycardia, and in the rapid heart of Graves' disease.

In regard to the exercises we learn that they are called "Widerstands-Gymnastik," or resistance gymnastics, and consist of slow movements executed by the patient and resisted by the physician or operator. A short interval is allowed after each movement, during which the patient sits down. The exertion employed must be very small, and should cause no increase in respiratory movements, flushing, or pallor. The patient should be loosely and lightly clothed, and instructed to breathe quietly. The resistance made should be of such a kind that the patient may always feel himself easily the master. The operator must not grasp or in any way constrict the limb, but should oppose by the hand held flatly. The movements are nineteen in number:

1. Arms extended in front of body on a level with shoulder, hands meeting; arms carried out until in line, and brought back to original position.

2. Arms hanging at sides, palms forward; arm flexed at elbow until tips of fingers touch shoulder, back to original position; one arm only moved at a time.

3. Arms down, palms forward; arms carried outward and upward until thumbs meet over head; back to original position.

4. Hands in front of abdomen, fingers flexed so that second phalanges touch those of opposite hand; arms raised until hands rest on top of head; back to original position.

5. Arms down, palms against thighs; arms raised in parallel planes as high as possible; back to original position.

6. Trunk flexed on hips: return to original position.

7. Trunk rotated to left, to right; return to original position.

8. Trunk flexed laterally.

9. As No. 1, but fists clenched.

10. As No. 2, but fists clenched.

11. Arms down, palms against thighs; each in turn raised forward and upward until arm is alongside of ear, then turned outward, and arm descends backward.

12. Arms down, palms to thighs: both together moved backward in parallel planes as far as possible without bending the trunk forward.

13. Thighs in turn flexed on trunk, opposite hand resting on chair.

14. Lower extremities in turn extended fully, and bent on trunk forward and backward to extreme limits of movement, opposite hand resting on chair.

15. Legs in turn flexed on thigh, both hands on chair.

16. Feet together; lower extremities in turn abducted as far as possible, and brought back to original position, opposite hand resting on chair.

17. The arms, extended horizontally outward, are rotated from the shoulder-joint to the extreme limits forward and backward.

18. The hands in turn are extended and flexed on the forearm to extreme limits, and brought back in line with arm.

19. The feet in turn are flexed and extended to extreme limits, and then brought back to their natural position.

Dr. Saundby says that these exercises are easily learned, and that nurses make very good operators, as they do not resist too much.

In conclusion the author holds that a system like Dr. Schott's, which has been slowly evolved and perfected by years of careful clinical work, comes to us claiming attention chiefly from its practical results and is, in Saundby's opinion, in no way discredited by any differences or doubts as to the proper theory upon which it is based. The latter only becomes important when new developments of the system are started, based on doubtful theories and lacking the support of his long experience.

And, finally, Dr. Saundby expresses his strong sense of the danger there is of checking the fair trial of this promising method by the hasty extension of it to cases forbidden by Dr. Schott and against which he especially warns us. Worked carefully and conscientiously on the lines laid down by its originator, it seems capable of being usefully introduced into our hospitals, into private practice, and especially into the practice of physicians at watering-places, where many cardiac patients go annually for the treatment of their rheumatic and gouty ailments.

WEATHER NEUROSES.

It is a well-known fact that some neurotic affections are more or less influenced, as regards both their origin and their intensity, by climatic conditions.

The lancinating pains of locomotor ataxia are commonly made worse by the appearance of cold and wet weather. In multiple neuritis, in many forms of myelitis, even in ordinary neuralgias, similar changes are often observed. The state of the weather perceptibly affects most cases of neurasthenia. There are neuroses, however, according to Dr. Loewenfeld,¹ of Munich, that depend almost exclusively upon certain conditions of the weather. The author classifies these disturbances under the suggestive name of weather neuroses. The symptoms are divided by him into two groups, the first of which comprise the sensory and the second the motor sphere. Pain and paræsthesia belong to the former and different degrees of weakness to the latter. The pains complained of by patients afflicted with "weather neuroses" are generally lancinating in character. The attacks may last from a few hours to several days. Weather neuroses may appear as independent affections or arise as complications of other nervous troubles. Dr. Loewenfeld believes that in most cases only peripheral nerves are affected, although he admits that central disorders are not necessarily excluded.

So far as is known the weather neuroses are functional, not organic, affections. Abrupt changes of temperature, barometrical variations, the sudden alterations from dry to wet weather, or *vice versa*, are

chiefly responsible for the rather obscure symptoms of this group of disturbances.

The prognosis is relatively favorable, especially in young people. In regard to treatment, the author has no particular remedies to suggest. Galvanism, massage, hydrotherapy, and similar measures often afford relief. Tonic treatment is generally indicated. Over-treatment is apt to be harmful.

BOGUS AUCTIONEERS AND BOGUS DOCTORS.

MANY years ago New York City contained a greater proportion of mock auctioneers and quack doctors than it does to-day. Legislation has been invoked and secured for the protection of the public on the one hand and that of the legitimate trader and practitioner on the other. That there still exists an abundance of charlatanism is only too well known to every honest physician, and it is keenly felt by every young medical man struggling to secure a foothold in this great metropolis by honorable means and hard work.

Business men have united in an association for the suppression of fraudulent auctions, and during the past week legal proceedings have been instituted against two firms accused of conducting a fraudulent business.

The injury done the community by fraudulent auctions is ludicrously small in comparison with that daily inflicted by the many pretenders in medicine. It seems almost a wonder that, even if physicians will not make an effort to maintain their rights, the public does not take up the matter and demand that one who advertises to cure an incurable disease and who takes your money without giving an equivalent is as much a pretender as he who imposes upon you a modern rug at an antique price.

News of the Week.

Leprosy in a Railway Employee.—Dr. Sibley recently exhibited to the Harveian Society of London a boy, sixteen years old, who was suffering from anæsthetic leprosy. He was born in India of English parents, and had lived in England for four years, working in the employ of a railway company.

The Medical Staff of the Italian Red Cross Society in Abyssinia consists of a chief surgeon and five assistants. The society has recently sent eight mountain ambulances to the seat of war and proposes to forward immediately a portable hospital with one hundred beds.

Professor Marie P. C. Sappey died in Paris on March 14th at the ripe age of eighty-six years. He was born at Bourg-en-Bresse, and received his degree in Paris in 1843. He studied and wrote much on anatomy and comparative anatomy, his best work being on the lymphatics of man and other mammals, as well as of fishes.

¹ Therapeutische Wochenschrift, February 23, 1896.

College of Physicians of Philadelphia.—At the meeting of the College of Physicians of Philadelphia, held on April 1st, Dr. Wharton Sinkler reported an interesting case of suppression of urine for more than nine days in a woman of sixty years, with an absence of symptoms of uræmia. Upon examination after death, some time subsequently, one kidney was found to be quite healthy, while the other was sarcomatous and had its ureter partially occluded by a calculus. In the discussion Dr. F. P. Henry pointed out that uræmic symptoms are prone to develop only when the urinary suppression is dependent upon serious damage to the structure of the kidneys, and not when the anuria is dependent upon the occlusion of the pelvis or ureter of otherwise healthy organs. Dr. C. B. Penrose reported the case of a woman who had been operated upon for the removal of a fibroid tumor of the uterus and in whom, without known infection or other complication, the temperature progressively rose until shortly after cessation of the heart beat it reached 109.5° F. Dr. J. M. DaCosta reported gratifying results from the hypodermic use, in aggravated cases of anæmia, of iron and manganese citrate in doses of three grains daily in a twenty-per-cent. solution.

Practical Skiagraphy.—Professor Cox, of McGill University, Montreal, recently demonstrated again the practical value of skiagraphy in surgical diagnosis. A girl was complaining of a needle which she said was lodged somewhere near her wrist but which could not be located by the most careful examination. The hand was then exposed to the X-rays for thirty minutes, and in the skiagraph thus obtained the needle was plainly to be seen.

The Prevalent Disease in Kansas.—Kansas is a prohibition State, and the drug store is consequently the only resort of the thirsty. Purchasers of liquor are obliged to make an affidavit that it is for medicinal purposes, stating at the same time the disease for which a cure is sought. An examination of the drug-store returns of Topeka for January discloses a prevalence of colds, over one-half of the affidavits on which liquor was sold being for "the disease of cold." Officers of the Temperance Union found one obstinate case of this complaint, that of a prominent business man, whose name was found in the application books of a drug store nine times in seventeen days, on each of which occasions he obtained a pint for the "disease of cold." Among the other maladies for which relief was sought in some form of alcohol were "the disease of old age," the "loss of an eye," and "cramp in the heel."

Jefferson Medical College.—Dr. Albert P. Brubaker has been elected adjunct professor of hygiene in Jefferson Medical College. Dr. Brubaker is well and favorably known as a clear and forcible lecturer and as an able and respected instructor. He has at different times been demonstrator of experimental physiology, demonstrator of experimental therapeutics, and instructor in materia medica, general therapeutics, and hygiene in Jefferson College. He is also professor of physiology in the Pennsylvania College of Dental Surgery.

Thyroid Gland for Lupus.—Dr. Herbert Marson reports in the *British Medical Journal* a case of lupus occurring in a young man, twenty years old, in which a complete disappearance of the disease followed the administration of thyroid gland extract. The treatment was continued for three months, and was combined with the administration of cod-liver oil.

Professor Behring has given the half of the Alberto Levi prize, recently awarded to him (\$5,000) to the Prussian government fund for the furtherance of research on serum treatment. The moneys received by the official control stations where the diphtheria antitoxin is tested before it is allowed to be sold will also be paid into this fund.

Death of Count Mattei.—Count Mattei, whose "remedies" for cancer and other ills became widely known a few years ago through being taken up and advertised by the English editor, Stead, died on April 7th in Bologna.

Against the Spitting Nuisance.—The Philadelphia Board of Health has undertaken to distribute as widely as possible the notice that "the habit of spitting carelessly and indiscriminately, as on the floor or ground, is a common means of spreading consumption. The expectoration of the consumptive becomes dried and mixed with dust, and then is easily carried into the air, and is breathed into the lungs. The habit, therefore, is not merely offensive but dangerous."

The City of Mexico has recently completed at great cost a new and elaborate system of sewers. Among other items this involved the building of a canal thirty miles long at an expense of \$15,000,000.

Obituary Notes.—DR. L. M. DE IESI, a graduate of Jefferson Medical College, died on March 16th at Zacatecas, Mexico. He was an Italian by birth and originally studied for the priesthood. Subsequently he changed his faith, and after his graduation was appointed a missionary to Mexico.—DR. SAMUEL R. KEELER died at his home at Goodville, Pa., on April 2d at the age of fifty-eight years. He was graduated from Jefferson Medical College in 1863.—DR. WILLIAM F. LACEY died in Danbury, Conn., on March 31st. He was seventy-three years old, and came of a family of physicians prominent in New England in the last century. He was an ex-mayor of Danbury. Forty years ago Dr. Lacey became famous by effecting a cure of tetanus.—THOMAS M. FRANKLIN, M.D., a graduate of the medical department of the University of New York City, class of 1847, died at his home, "Glenrear," Greenwich, Conn., on Sunday, March 22d. He was one of the physicians to the Eastern Dispensary from 1847 to 1851; a ward cholera physician in the early summer of 1849; resident assistant physician to Centre Street Cholera Hospital; assistant physician at the Government Hospital for the Insane, Washington, D. C., from 1865 to 1872; medical superintendent of the New York City Lunatic asylums, Blackwell's and Hart's Island, from 1878 to 1886. He went to Greenwich in 1887, where he led a quiet life. He leaves a wife and one son, Dr. Spencer Franklin, formerly of Greenwich.

Hospital for Contagious Diseases in Philadelphia.

—A movement has been set on foot for the establishment in Philadelphia of a pay hospital for the treatment of contagious diseases, and committees have been appointed by the County Medical Society and the Women's Health Protective Association for the consideration of ways and means for effecting this end. A fund of \$2,300 has already been accumulated for such a purpose. The Municipal Hospital is at present the only institution in the city that will receive patients suffering with contagious diseases, but its accommodations are usually strained to the utmost and they are perhaps not exactly those that a fastidious patient would care to select. The need seems therefore urgent for some place to which visiting strangers and the well-to-do of the community may have access if stricken with a contagious affection and the movement under consideration is in every way to be commended and encouraged.

Death of Dr. Jacob M. Gemmell.—Dr. Jacob M.

Gemmell died at his home at Philadelphia on March 21st at the age of eighty-six years. He was graduated from Jefferson Medical College in 1810. After practising medicine for a number of years in his native place, Alexandria, Va., Dr. Gemmell in 1859 became physician to the Pennsylvania Railroad and located at Altoona, Pa. Here he remained until 1876, when he removed to Philadelphia.

Women Physicians for the female insane are advocated by Dr. Louise Rabinovitch, formerly of the New

York City Asylum for the Insane at Blackwell's Island, who addressed the meeting of the Women's Christian Temperance Union recently held in Brooklyn and made an appeal for the insane. She advocated the appointment of women on the State Board of Lunacy and as physicians for the treatment of insane of their sex.

The Metric System of Weights and Measures.—

A bill has been favorably reported in the House of Representatives providing that in all departments of the federal government business requiring the use of weights and measures shall be conducted on the metric system after July 1, 1896, and extending this system to the commerce of the country on January 1, 1901. Persons favorable to the measure are urged by its backers to petition their congressmen to vote for it.

Tuberculin Redivivus.—It is reported from Berlin

that Koch has recovered his spirits and his faith in tuberculin, and is soon going to publish the latest results of his experiments and practice with that remedial agent. He has largely modified tuberculin, both in composition and application in his private and public practice. He believes that his forthcoming book will contain enough facts to induce the profession to take the matter up once more.

Open-Air Treatment of Tuberculosis.—There are

now six sanatoriums in Germany at which consumptives are treated by constant exposure to air at a low temperature. Currents of cold air are allowed to pass through the bedroom at night, and during the day as much of the time is spent in the open air as possible.

The Electrical Exposition to be held in this city next May will have among its attractions the collection of early books on electricity owned by Dr. Park Benjamin, which constitutes one of the finest libraries in the world on this subject.

The New York Homœopathic Medical College

has received a gift of \$5,000 from ex-Governor Flower to endow five beds, and a Mrs. Kundhardt has given \$15,000 for a memorial ward.

Sir William MacCormac has received from the

Prince of Wales the appointment of Medical Officer-in-Chief to the St. John Ambulance Brigade.

Rabies is said to be very prevalent in Portugal, owing to the great number of vagrant and ownerless dogs at large.

Guy's Hospital has "closed beds" for lack of

funds. A determined effort is being made by the friends and alumni of this ancient and honorable institution to secure a sum which will make good the recent depreciation in its income securities.

Dr. Joseph Beals, a well-known dentist in Green-

field, Mass., and a prominent spiritualist, died at his home on March 27th, aged 74 years.

Refused Admittance.—The same unaccountable

taste and tendency which leads him to run alongside of the hearse of funerals bound for Calvary Cemetery must have been at work in the person of Johnny Look-up, an eccentric, deformed boy, well known to the undertakers of the East side, when, on being injured the other day, he applied for treatment at the door of the Bellevue Morgue. "You are not yet quite ready for treatment here, Johnny," said Morgue-Keeper White, as he directed him around to the surgical waiting-room.

Association of American Physicians.—The next

annual meeting will be held in Washington, D. C., April 30th, May 1st, and 2d.

National Confederation of State Medical Exam-

ining and Licensing Boards.—The sixth annual meeting of this organization will be held in room No. 1, Hotel Aragon, Atlanta, Ga. (which offers reduced rates), Monday, May 4, 1896, at 10 A.M. The objects of the confederation, though purely of an advisory nature, are to discuss questions that pertain to State licensure in medicine, with a view to a comparison and improvement of methods, a collection and dissemination of information on the subject, and to consider any and all propositions that have for their purpose the advancement of the standard of medical education in the United States. The officers of the confederation, therefore, beg to extend a cordial invitation to members of State examining boards and all ex-members of State boards, and especially to every physician and educator who is friendly to the objects sought, to attend the meeting and participate in the proceedings.

Albany Medical College Alumni.—The twenty-

third annual meeting of the Association of the Alumni of the Albany Medical College will be held in Albany on Tuesday, April 14th.

The Medical-Practice Law of Kentucky.—The present law regulating the practice of medicine in Kentucky, says the *Journal of the Medical Sciences*, has resulted in driving out the quacks, with their placards, signs, and showbills, and has greatly lessened the revenue of many of the newspapers of that State. The law is all right and a great blessing to the unfortunate afflicted, who have heretofore been robbed by these ignorant pretenders, only upheld by their liberal advertising.

The Fourth Intercolonial Medical Congress of Australasia was held in Dunedin, New Zealand, February 3 to 10, 1896, under the presidency of Dr. F. C. Batchelor. The meeting was largely attended and many papers of practical interest were read and discussed. The next session of the congress will be held in Brisbane, Queensland, under the presidency of Dr. John Thomson.

The American Academy of Medicine, whose sessions are held in the same place as those of the American Medical Association, will meet this year on May 2d and 4th, at Atlanta. The provisional programme contains twenty-seven titles of papers to be read. The secretary of the academy is Dr. Charles McIntire, Easton, Pa.

The Roentgen Rays, in their medico-legal possibilities and their bearings upon medical and surgical diagnosis and practice, are to be discussed at length in the Section on Neurology and Medical Jurisprudence of the American Medical Association at the Atlanta meeting.

The Miscalled International Congress at Moscow promises to be a Franco-Russian love-feast to which a few Germans will be admitted on the condition of good behavior. The attendance from English-speaking countries, since the use of English is forbidden at the congress, will of course be very small. The loss to the stay-at-homes will not perhaps be very great. As the *Boston Medical and Surgical Journal* remarks: "There are only two strictly medical reasons for attending such congresses: One, that of making professional acquaintances and of absorbing information from the papers and discussions by foreigners—representatives of his own country one can hear often enough at home; the other, that of enjoying the satisfaction of hearing one's self elucidate original theories or relate interesting cases. From the first of these privileges the physician who understands only English is debarred and, if he is compelled to put his own paper into a language he does not understand, he is also cut off from the second. It would be just as well, and less expensive and fatiguing, to stay at home and read the proceedings of the congress when translated."

The Priestly Hydrotherapist, Kneipp, prescribes for his patients at the rate of three a minute. As the prescription is always the same, no matter what the disease, this is not such a remarkable feat after all.

The American Climatological Association will meet at Lakewood, N. J., on May 12 and 13, 1896.

Typhoid Fever in Western New York.—A typhoid-fever epidemic at Elmira has been reported with a somewhat startling death roll. It is asserted that the sewage of a number of towns and cities is poured into the Chemung River, which can have only one effect—namely, that of polluting and poisoning its water. Ice, too, is cut from that river and used at Elmira. It is a well-known fact that freezing does not destroy the poisonous germs of ice made from polluted water. We assume that here are ample causes for this outbreak of an infectious disease which is recognized as preventable. The prompt action of the health department in Buffalo has served to check a threatened epidemic through infected milk. A milk dealer was detected in delivering infected milk. He was prevented from further service to his customers and so the spreading of the disease was cut short. Had the health department of Elmira taken similar precautions, sickness and death to an alarming degree might have been prevented. These two lessons of cause and effect—of infection and prevention—teach their own moral.—*Buffalo Medical Journal*.

The Prevention of Criminals.—In a recent lecture before a teachers' association of Turin, Professor Lombroso dwelt upon the practical advantages of a knowledge of the science of criminal anthropology to those who have to do with the training of the young. The inclinations of the child, he said, are almost the same as those of the adult criminal, but usually disappear as age advances. In some instances, however, these characteristics continue and become more and more marked. In these cases there are associated physical peculiarities, and it is in the detection and pointing out of these possible criminals of the future that the speaker believed the teacher can do so much truly useful work.

The Jenner Centenary in Berlin.—A committee has been formed in Berlin for the celebration of the Jenner centenary on May 14th. Among the members are Professors Virchow, Koch, Leyden, Bergmann, Gerhard, Koenig, and others. The programme includes an exhibition of portraits, medals, old and new instruments, writings, etc., bearing upon Jenner's great discovery, and also a celebration on May 14th, intended not only to honor Jenner himself but also to protest against the anti-vaccination agitation.

Inoculation of Cancer.—Dr. Guernonprez, of Lille, reports a case of professional inoculation of cancer. A surgeon who was treating a number of patients with epithelioma of the uterus had an irritable spot of acne in the temporal region, which he often scratched. One day the eyelid was scratched. Subsequently a small tumor appeared on the spot and gradually extended to the temporal region. It was an epithelioma. Guernonprez himself, while operating to remove an epithelioma from the face, had his nail injured by a sudden movement of the patient. He quickly washed the part and removed the injured portion of the nail. Subsequently a small warty tumor appeared, which proved very rebellious to treatment, but finally disappeared after nineteen months of attention.

Hypnotic Exhibitions.—The travelling "professors" of hypnotism have recently added new attractions in the way of exhibitions of prolonged hypnotic slumbers. One of these men recently opened a week's engagement in an Indiana city, putting a young man to sleep at the first performance, with the declaration that he was not to be awakened until the final exhibition at the end of the week. At the instance of a number of physicians, the Humane Society had the man arrested on the charge of cruelty to a child, his subject being a minor. The performer expressed great anxiety concerning the consequences to his subject of being awakened too early, for he said he was under a six-day spell and would surely die if released before that time. A similar case of six-day slumber, of which this one was a poor imitation, has called forth some indignant protests in England. The exhibition was given at the Royal Aquarium in London. A man was hypnotized, and after being sealed up in a stout casket or coffin, was consigned to a grave nine feet deep before an interested audience. Seven or eight feet of earth were then shovelled upon the body, a shaft being left open in order that respiration might take place, and also to allow the public to see the man's face during the time he was entombed. After six days the man was dug up and awakened before a crowd of people. Here is an excellent opportunity for dime-museum proprietors, which they will doubtless embrace, unless they can be prevented by the police.

A Singular Escape.—An insane woman in this city a few days ago threw her young child out of a window of her room on the third floor and then jumped out herself. Neither she nor the child received any injury.

Miss G. T. Morrill, of Wolcott, N. Y., has just received the degree of doctor of philosophy cum honore from Heidelberg University. She had attended lectures in Berlin, Leipsic, and Zurich, but was not permitted to be enrolled as a candidate for graduation until she went to Heidelberg last autumn. Miss Morrill is the second woman to receive a degree from this university.

Russki Arkhiv, or the *Russian Archives of Pathology, Clinical Medicine, and Bacteriology*, is the title of a new monthly journal in the Russian language, published at St. Petersburg under the editorial charge of Professor Podvysotski, of Kieff. The first number contains articles on "The Question of the Identity of Malarial Infection in Man and Animals," by Professor Danilevski; "The Treatment of Empyema by the Replacing of the Purulent Effusion by an Indifferent Fluid," by Professor Devassheff; "Some Disputed Points in the Treatment of Diphtheria," by Professor Philatoff; "The Experimental Production of Amyloid Change in the Liver in Animals," by Dr. Maximoff; "The Preparation of Diphtheria Antitoxin in the Bacteriological Institute of Moscow," by Dr. Berestneff; and "The Charcot-Leyden Crystals in Bronchial Asthma," by Dr. Kishenski. There are also two critical reviews on "Orrhotherapy," by Professor Metchnikoff, and on "The Question of Parasitism in Cancer and

Other Neoplasms," by the editor. The third section is devoted to abstracts and reviews of new books. Short abstracts in French of the original articles are appended, so that the journal is not altogether a sealed book to the outside medical world, but we regret that a scientific review of such excellence should not be written entirely in a tongue known to educated men everywhere. The articles are illustrated with numerous colored plates and woodcuts in the text. The journal is one that must inevitably take a high rank in medical periodical literature, and furnishes another evidence of the scientific spirit that pervades Russia of the present day.

Isolation of Consumptives.—Southern California, which has been likened by the admirers of its climate to the Riviera, is in danger of growing too like the latter in another respect, namely, as the home of the tubercle bacillus. In many places along the Riviera the once sturdy natives have been nearly exterminated by tuberculosis, contracted by washing the linen of the visitors and in other ways. In the hope of preventing this the town council of Alameda has passed an ordinance requiring physicians to report patients ill with consumption, in order that they may be isolated. Room isolation is meant, the family being required to give the patient a room to himself, and to observe such rules regarding sanitation as will minimize the danger of communicating the disease to others. If this measure appears to work well it will doubtless be applied to the towns farther down the coast, where tuberculous patients are more wont to congregate.

Foreign Medical Diplomas of Women Recognized.—It is reported from Vienna that an order issued by the minister of public instruction has been published, admitting women who hold foreign medical diplomas to registration in Austria.

The Medical Staff of the British Army numbers six hundred and fourteen persons. The total cost of this department is about \$1,000,000 per annum.

The Druggists of Barcelona threaten to deal no more in patent medicines of American manufacture in case the United States Congress passes a resolution in favor of Cuban belligerency.

The Canadian Senate has a medical member in the person of Sir William Hingston, who was recently appointed to a seat in that body.

Death from Researches in a Bacteriological Laboratory.—A medical student named Mansvetoff, who had been engaged in researches on glanders in Professor Vorontsoff's laboratory in the Medico-Chirurgical College, St. Petersburg, contracted the disease in some unexplained manner and it rapidly proved fatal, the lungs being affected.

Dr. Rosmini, director of the Ophthalmic Institute in Milan, died recently at Nervi. He was born in Milan in 1835, and received his medical degree from the University of Pavia.

Dr. Brouardel, professor of medical jurisprudence at the University of Paris, has been appointed dean of the medical faculty for the ensuing three years.

The **Cholera Epidemic in Russia** is officially declared to be at an end, no cases having been reported since February 24th.

Small-Pox is reported to be increasing in the southwestern counties of England and in South Wales.

An International Commission in Insanity.—Notice has been given to the English Parliament of a resolution to the effect that, in the interests of the general welfare, it is desirable to provide for the meeting of an international commission to study the causes of insanity, which is said to be greatly on the increase in England.

The **British Medical Register** for the present year, which has just been issued, contains the names of 33,601 medical practitioners, of whom 27,392 are practising in Great Britain and Ireland.

Professor Leyden, of Berlin, is now von Leyden, having recently received from the German Emperor a patent of nobility.

The **French Congress of Alienists and Neurologists** will hold its annual meeting at Nancy on August 1st and the following days. The questions for discussion are: "The Pathogeny and Pathological Physiology of Hallucinations of Hearing," "The Symptomatology of Tremors," "The Confinement of Lunatics in Special Institutions," "The Treatment of Lunacy," and "Legislation for the Insane."

Anti-Tobacco Laws.—In New Hampshire it is forbidden for any one but a minor's parents or guardians to give him tobacco or cigarettes. In Missouri there is a cigarette local-option law, each town having the right to prohibit the sale of cigarettes to minors.

A Medical Centenarian.—On March 16th, Mr. William Salmon, of Pennlynn Court, Glamorganshire, who is a member of the medical profession, completed his one hundred and sixth year. Mr. Salmon, who is the son of a medical man, was born in Suffolk in 1790. He became a Member of the Royal College of Surgeons of England in 1809, the year Mr. Gladstone was born. In early life Mr. Salmon was an army medical officer, but, though it was then a stirring time for the British army, he seems not to have seen any active service. He afterward married an heiress, thus becoming the owner of Pennlynn Court and the Garth. He has been a magistrate for the county of Glamorgan for fifty years. Mr. Salmon is not only the oldest member of the medical profession in Great Britain, but is believed to be the oldest Freemason in the world. He has had eight children, only one of whom (a daughter) is now alive. According to an account in a local newspaper he sleeps well, rises at noon, and goes to bed at nine o'clock. He dines at six, and Sir Benjamin Ward Richardson may be interested to know that he takes two glasses of wine at his evening repast. He gave up smoking at the comparatively tender age of ninety. We are sure the whole profession will join us in the hope that Mr. Salmon's life may be prolonged for many years.—*British Medical Journal*.

The **Typhoid Bacillus** retains its vitality even when dried for a long period. According to some experiments of Uffelmann, it retains its virulence when kept in dry earth for twenty-one days; in street-sweepings, thirty days or more; in sand, eighty-two days; on wood, thirty-two days; and on linen, over sixty days. The microbes retain their power of growth still longer in moist media. Uffelmann asserts also that typhoid bacilli may be carried by the air as well as by the clothing, and that they are thus capable of infecting milk, water, and various foodstuffs, and that typhoid fever is therefore not solely a water-borne disease.

Professor Roentgen has been created by the Prince Regent of Bavaria a knight in one of the orders of that kingdom, and he is now in consequence Professor von Roentgen. The University of Würzburg has also conferred upon him the honorary title of doctor of medicine.

A Workingmen's Medical Aid Society.—The Rome correspondent of the *British Medical Journal* describes the aims and methods of a society which has lately been established in Milan for providing medical aid to artisans who may sustain injuries in their occupations. For this purpose the society will provide medical services, necessary apparatus, etc., in the factories, according to their importance and position. Special services will be instituted for the transport of the injured to the hospitals or to their own homes. Ambulance instruction will be given to the workers in the large factories, and dispensaries will be provided for the treatment of wounds. The society hopes to be able later on to build a convalescent hospital for those badly injured or to build a special hospital for their treatment.

Vital Statistics of Philadelphia.—For the week ending March 28th the number of deaths reported to the Philadelphia Board of Health was 525, of which 189 were of children under the age of five years. The most conspicuous causes were as follows: Pneumonia, 101; pulmonary tuberculosis, 54; diseases of the heart, 31; senility, 20; inanition, 18; carcinoma, 17; convulsions, 17; diphtheria (not including membranous croup, 8), 17; marasmus, 17. The numbers of cases of diphtheria, scarlet fever, and typhoid fever for the week were respectively 65, 21, and 35. According to the report of the Pennsylvania Society for the Prevention of Tuberculosis there has been a marked decrease in the number of deaths from pulmonary tuberculosis in the city of Philadelphia during recent years, as a result in part of improved methods of treatment and in part of efforts to prevent its spread by communication. In 1880 there were 342 deaths per 100,000 of population; now there are not more than 220 in the same number. It is believed that if satisfactory hospital accommodations were provided for tuberculous patients the death rate would be still further reduced.

Surgeon-Captain Hiliard, who happened to be in the Ashantee expedition and so prescribed for Prince Henry of Battenberg, has received from the Queen the decoration of the order of St. Michael and St. George.

Surgical Suggestions.

Glaucoma.—Furthermore, after enucleation ophthalmia, either in the course of or at the beginning of the disease, bacteriological examinations of the nerve or of the organ itself were negative. On the other hand, any stimulation whatever of the ciliary nerves of one eye was followed in the other eye by disturbances appreciable on microscopic examination.—GROENOUW AND DUFOUR.

Peritonitis.—I believe that the gonococcus in its virulent state, before it has been for any length of time in the pus of a pyosalpinx, is perfectly capable of infecting the peritoneum, and will, if opportunity is afforded, produce the most virulent peritonitis—peritonitis that leads to rapid death, with marked symptoms of profound septic infection.—FRANK.

Trichiasis.—Kenneth Scott (*Annales d'Oculistique*) says that he has obtained excellent results from the following simple operation: Make an incision of the tarsal cartilage in the conjunctival surface parallel to the palpebral border, but two millimetres removed from it. Let the incision include the entire extent of the lid and completely divide the tarsus, respecting only the skin. Turn the ciliary border outward and fix to the cutaneous surface of the lid at three points by means of silver wire sutures.

Infantile Intussusception.—Dr. Wiggin before the Academy of Medicine said that intussusception is really a form of strangulated hernia. The subacute variety is an irreducible hernia. If laparotomy is performed within forty-eight hours seventy-eight per cent. of the cases should recover.

Cervix Laceration.—Dr. Goldspohn, of Chicago, thinks that a certain amount of laceration of the cervix is attendant upon natural labor. If the tear does not extend more than midway between the external and internal os, it is not pathological and should be left alone; if it extends higher up, it leads to ectropion and often retroversion and demands operative measures.

Epistaxis.—Dr. T. A. Hall says the powder of fungus myces (F.), commonly known as "devil's snuff," has invariably stopped epistaxis when snuffed up the nostrils.—*Va. Med. Monthly*.

Constipation in Infants.—

R Tinc. nuc. vom	℥ss.
Tinc. belladonnæ	℥lv.
Inf. sennæ	℥xx.
Inf. gentianæ co.	ad ʒi.

M. ft. haustus. S. To be taken three times a day before meals by a child from eight to twelve months old.

—EUSTACE SMITH.

Vinegar as an Antidote to Carbolic Acid.—Dr. Carleton, in a note published in the *Deutsche Medizin-Zeitung*, February 17, 1896, advocates the use of common vinegar in carbolic-acid poisoning. He states that applied to the skin or mucous membranes vinegar promptly counteracts the toxic effects of carbolic acid. In internal poisoning he advises that vinegar and water in equal parts be freely imbibed and that following this the stomach be promptly emptied.

Lithæmia and Diseases of Women.—In an article by Dr. Mann, referred to by the *International Medical Magazine*, we are told that the urinary, alimentary, and genital organs situated in the female pelvis are intimately associated in function as well as in position. The relation of position may be demonstrated by the course of gonorrhœa, which may infect the urinary

tract, even as far as the kidneys, and the rectum, as well as the genital canal. This is also true of septic disease, though to a less degree. Through the nervous and vascular connections, the secretions of the different glands found in or connected with these organs may be more or less reciprocally affected. The victims of morbid conditions depending on the close interdependence of function and disease in the nearly associated pelvic organs complain of many symptoms, subjective and objective. They tell us of pains and aches in various places, many of which we call reflex. They complain of menstrual disturbances, vaginal discharges, backaches and frontaches, troubles with the bladder and rectum. They suffer from insomnia and dyspepsia; and, above all and before all, they tell us that they are nervous. Often the spirits are depressed and there is sometimes a fear of impending insanity; headaches, especially occipital, and intercostal neuralgia are common. A physical examination often shows no serious lesion of the pelvic organs. An examination of the urine will give much information; usually the quantity is below the normal, the reaction excessively acid, and uric acid is present in abnormally large quantities. At times the urine will be clear, limpid, and of low specific gravity. The blood also should be examined, for anæmia is one of the most important associates or causes of excessive uric-acid output. In cases presenting these combinations, the question to be decided is whether the trouble is primarily with the uterus and ovaries and all the rest reflex or secondary, or *vice versa*. It is possible to group such cases under the term lithæmic or under the term uric-acid diathesis; but the best plan is to consider them as cases of general disturbance of nutrition, and then we shall be forced to study each case to find out exactly the origin of the disturbance. The pelvic lesions may be the cause or they may be the result. We can get more help in understanding these cases by remembering the close relations which exist between the circulation of the pelvis and that of the liver; also by remembering the dependence of the kidneys upon the proper performance of the functions of the stomach and liver; and again by remembering the intimate nervous connection between the uterus and these other organs. If the trouble starts in the stomach from an error in diet, or from overwork or nervous strain, there result imperfect metabolism of the food products, the formation of poisonous substances, the imperfect action of the skin, kidneys, liver, and bowels, failure to excrete the toxins, and the production of an auto-intoxication resulting in nervous and functional disturbances. This train of events, slightly modified, may be due to an abnormal urine, to rectal disorder, or to primary uterine disorder. The special causes will be found in the climate, diet, social condition, the wear and tear, the hurry and rush, and the fatigues and strains of modern life.

Resection of the Knee.—Pack, of Liverpool, was the first to resect the knee on July 2, 1871. Before the days of antiseptics the mortality varied from twenty to fifty per cent. (Koenig). Ollier recommends leaving the lateral ligaments; Championnière advises removing them. To avoid injuring the popliteal artery George Fenwick, of Montreal, proposed in 1885 to make the section of the femur convex and that of the tibia concave. Jules Boeckel in 1889 showed the advantages of curettage of the medullary canal in cases of fungoid arthritis. Gurdon Buck and Richet practised metallic suturing. Championnière formerly employed catgut, but now uses silver wire. Ollier employs either silver, platinum, or galvanized iron, while Boeckel has given up bone suture altogether.—BRODIER, *L'Indépendance Méd.*, December 25, 1895.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PARLIAMENT—SMALL-POX AT GLOUCESTER—THE ARMY MEDICAL DEPARTMENT—POOR-LAW BILL—WATER SUPPLY OF LONDON—COLLEGE-OF-SURGEONS REPRESENTATION—IRE OF PHARMACOLOGISTS—LYMPH SCROTUM—BRAIN TUMORS—PONTINE HEMORRHAGE—SO-CALLED LINGUAL VARIX.

LONDON, March 20, 1896.

In the House of Commons last night the government to a question about the serious outbreak of small-pox at Gloucester replied that four hundred and ninety five cases have been notified, of which three hundred are still under treatment, and ninety-three have been fatal. It is well that this statement should have been made in Parliament, as it ensures that the object lesson which Gloucester has furnished to the country will be visible wherever a good newspaper circulates. Gloucester's folly in listening to the antivaccination fad is now seen to be dangerous. Some places in the neighborhood of Gloucester are much in fear of becoming infected.

On Monday the under secretary for war made a lengthy statement on the army, when the difficulty of keeping up the strength of the medical department could not be concealed. He admitted that the confidence of the profession was a necessity, and said the war office had endeavored to find out the cause of the growing unpopularity of the army medical service. He mentioned that several explanations had been submitted and that time was required to decide among them. Dr. Farquharson pointed out that the social status of army surgeons had actually been lowered, especially since the abolition of the regimental system. He suggested a partial return to that system. This would please a large number, but I fear would not, if indeed it were possible, prove a complete remedy. It is well that the authorities should feel that something must be done.

On Wednesday the Commons spent some three hours over the poor-law superannuation bill, which is regarded as an important one to the medical officers, as it will enable them to secure pensions in return for a small percentage of their salaries. The bill was read a second time and referred to one of the grand committees. In the mean time the question is to be considered whether it is desirable to extend it to Scotland and Ireland. There can be no doubt that its provisions would be equally beneficial to those countries and to Ireland especially so. Whether the Irish poor-law doctors, who did not take the trouble to vote for their greatest advocate at the election to the Medical Council, will exercise pressure now in favor of themselves seems almost doubtful.

The water supply of London continues to occupy attention. A curious revelation lately occurred. As the companies read their acts, they hold that consumers must lay their pipes below a certain level. But some companies had their mains above this point, and this has been the cause of much trouble. The report of an official inquiry, conducted by General Scott, is of a most damaging character, but the companies have survived worse dangers. If we could only feel confidence in the County Council, the water supply might be entrusted to that omnivorous body, but it has managed some matters so badly, and at such frightful cost, that the rate payers are afraid of it. Perhaps a special body will after all have to be created to discharge this first of municipal duties.

The council of the College of Surgeons has pronounced against the claim of members to seats at the

board. This is just as I expected. The council declares that they "represent the body corporate of this royal college, and consequently its members as well as its fellows. It is the opinion of this council that no further representation of the members is desirable." It is no doubt true that the council represents the members as a part of the body corporate. But the other part of this body corporate—the fellows—is the only part that elects the council. So, should the interests of the two parts clash, only one side is represented. But these interests should not clash—in fact there should be no interests in the matter save the good of the college. But entrance into the council implies honor, power, emoluments. All these the fellows have monopolized and are reluctant to share with members. There is nothing like a monopoly to make men selfish. The fact that fellows must first be members seems to be overlooked. A more important fact in this connection is that the fellows, as holders of an additional distinction of the highest academical value, are necessarily the most influential part of the body corporate and that individual fellows would have superior claims as candidates, so that the utmost extension of the franchise could fail to introduce into the council more than a very small minority of members who were not also fellows. And yet the fellows cannot see this, but, blinded by their possession, hug this precious privilege of electing the council as if it were the one distinction of the fellowship.

The College of Surgeons has accepted without demur the proposal of the sister college to omit pharmacology as a separate subject from the curriculum. The irate protests of a section of our pharmacologists have therefore been in vain, though it is curious to observe that they seem more concerned for the shadow of their favorite name than for the substance it should signify. One of these gentlemen predicts the speedy advent of a generation of legally qualified practitioners ignorant of therapeutics, unable to write the simplest prescription, and therefore compelled to fall back on some one's antisciatin for sciatica, antipilin for piles, and other like substances made in Germany, as the pharmacist's occupation will be gone. Another gentleman confesses his shame at the ignorance of the fellows of the College of Physicians of the advantage of a knowledge of therapeutics. And so on, and so on. Surely this sort of thing partakes of caricature. Pharmacology may smell as sweet under any other name, at any rate to all but a few pharmacologists. It has been taught before they assumed the title. How, indeed, did they themselves learn their subject, if, as they tell us, it is only to be learned from lectures? They will perhaps admit they attended lectures on therapeutics which included it—and they themselves but a few years since used the term therapeutics for what they now call pharmacology. All that passes under this name was, I know, taught at some of our chief colleges by the professors of materia medica and therapeutics five and twenty years ago—perhaps more. I can vouch for that date. So perhaps what has been will be, and we may live in hopes that the predictions of ignorance and ruin may not be fulfilled.

At the Clinical Society meeting on Friday last, Mr. Golding Bird brought forward cases of lymph scrotum and lymph varix. One was in an athletic young Londoner, who had never been abroad. Vesicles the size of millet seeds formed, burst, and discharged milky fluid. Nothing abnormal was detected in the blood. The right half of the scrotum was excised and leaking points of divided lymph vessels ligatured. A good recovery followed, the remainder of the scrotum being rather tightly stretched over the testes and but few lymph vessels being visible in the perineum. Another case was related and some published ones referred to.

A case of neoplasm cyst in the region of the angular gyrus, which had been operated on, was brought forward by Dr. Colman and Mr. Ballance. The history and post-mortem were succinctly related and the symptoms duly discussed.

Dr. Buzzard (President) had had this case under his care for a month, and had not regarded it as a very favorable one for operation. But, he said, the question of interference with these brain tumors was a difficult one. No doubt when the tumor could not be removed the operation might prolong life, but it was a formidable procedure, and he hoped we might find means to relieve tension without resorting to it. Still he admitted the amount of relief was well purchased at the price. When there were indications of the tumor being encapsuled he hailed the help of the surgeon, but these cases were not numerous. Dr. Starr said he had found on analyzing statistics that only seven per cent. of cases of cerebral tumor were removable. Mr. Ballance admitted that the operation was dreadful, but it was only undertaken for a very dreadful disease and he saw no way of relieving tension without operation until we could discover something antagonistic to malignant growth.

Dr. Lucas Benham related a case diagnosed as hemorrhage into the pons, which was treated by bleeding and recovered. Considerable difference of opinion was manifested as to the diagnosis, and more than one alternative was suggested, and the question whether the bleeding brought about recovery was also raised. The difficulties of diagnosis of such cases are generally recognized.

So-called "lingual varix" is the occasion of "a storm in a teapot" among the laryngologists. One of the younger ones questioned the existence of the varicose veins at the base of the tongue to which much significance had been attributed by others. Some of the latter replied in *The Lancet* and to these a rejoinder was issued signed by several. Of course the dispute could not rest here, and so we have a "very pretty quarrel going on." Some of the leading laryngologists have up to the present remained inactive, but who knows how soon they may rush into the fray? Those (if any) who do not may hereafter perhaps pronounce judgment on the case.

COCAINE IN SEASICKNESS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the *MEDICAL RECORD* of January 25, 1896, I notice a communication from Dr. A. D. Rockwell, of New York, entitled "The Preventive Treatment of Seasickness." Having had some experience in treating this malady during a period of four years, while serving as an assistant surgeon in the United States navy, I should like to state what good results I obtained from the administration of muriate of cocaine.

A patient applied one morning at sick call a few days from port, after we had encountered very heavy weather, and when questioned as to the nature of his complaint he stated he was seasick. He was one of the band, played the alto horn. When asked if he was too sick to attend to duty, he answered as follows, being an Italian: "Yes, doctor, I 'fraid I spoil the instrumenta." He was admitted to the sick list.

His bowels were constipated, so I prescribed two cathartic pills at once. As soon as they had acted he was given five minims of a four-per-cent. solution of cocaine muriate per os, repeated hourly until three doses had been taken. He had eaten scarcely anything for two days, as his stomach rejected everything.

The patient speedily recovered; vomiting, which had been severe, entirely ceased after the first dose of

cocaine, and by the time he had taken the third dose all nausea had disappeared and he was sent to duty.

During the remaining thirteen days of the trip, which was a rough one, he had no nausea or vomiting and ate his three rations daily with relish.

One day before going to sea again I sent for this same musician, gave him two compound cathartic pills, although his bowels were open, and prescribed cocaine muriate in the doses as before, three times during the day at intervals of three hours.

As a result of this treatment he had no symptoms of seasickness during the passage, which was fully as rough as before, the duration being ten days.

There were a number of young apprentice boys aboard, their ages ranging between fourteen and eighteen years. The majority was always seasick the first days out and some sick enough to be admitted to the sick list. I treated them in a similar manner as the first case, and with equally good results.

From my experience, therefore, I believe that constipation, from whatever cause, has much to do with seasickness, by causing poor digestion and thereby an irritable stomach.

A person on terra firma if constipated usually has an "upset stomach," as patients express it, and probably some vertigo. Add to this, then, a movable surface upon which to walk, a small, usually poorly-ventilated stateroom (air ports frequently having to be kept closed), probably odors emanating from bilge water, and almost always the result is seasickness.

Fellow passengers with whom I have conversed have told me that to avoid seasickness they regularly take a brisk cathartic the day before sailing and frequently ward it off, or if it does occur it lasts but a day. But in the event of no medication and if constipated when sailing, they suffer from seasickness during the entire passage.

I have not tried bromidism, as Dr. Rockwell recommends, but can see wherein the benefits may lie.

ROBERT BOYD, M.D.

GRAND CAYMAN ISLAND, BRITISH WEST INDIES,
March, 1896.

SPECIAL MEDICAL ADVERTISING IN THE DAILY PRESS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: An editorial under the above caption in the *MEDICAL RECORD* for March 28, 1896, gives evidence that its author has not fairly tasted the sweets of newspaper advertising.

I have received enough newspaper attention to equip me pretty well for a narrative of personal experience in this matter, so kindly listen for a moment.

The only case that ever came to me directly or indirectly from newspaper sources was one in which I was threatened with a malpractice suit later.

In early days of inexperience I once cheerfully gave an interview to the reporters concerning an interesting hospital case. My superior, who was the principal in the case, refused in his brusque way to give them any information at all. I did not see reporters after that, but to reward me for my original kindness they gathered information daily from hallboys and attendants and mentioned me as the surgeon in the case, withholding the name of the principal. The result was very naturally an estrangement between the principal and myself which could not well be settled, as pride stood in the way of making any explanation.

Sometimes it has been impossible to avoid sharp reporters. One of them came to my office some time ago and presented the card of a lawyer, stating that he was attorney for one of my patients. I trusted him

and gave a full and explicit account of the case, which account promptly appeared as a whole column interview in the next Sunday's edition of a newspaper that has adopted the policy of obtaining news at any cost and by any means. The result was a divorce, an attempted suicide, and troublesome court work for me.

In an article which appeared in a Sunday newspaper about two years ago my name was associated with those of two or three men much more prominent than myself, in a half-page description of a disease which was greatly interesting the public at that time. The article, which purported to be an interview, was profusely illustrated with cuts of pathological specimens and instruments. I instantly recognized my part of it as the reproduction of one of my contributions to the MEDICAL RECORD, but it appeared as an original contribution to the newspaper. On making inquiries I learned from one of the staff of the paper that the article had been made up and presented by a reporter who was also a medical student and who had thus hoped to turn an honest penny.

I have never been ambitious for fame of any sort, because it interferes too much with personal comfort, but what little fame I have gained from plain daily labor has been pretty much wiped out by this so-called newspaper advertising.

One of my books was fully reviewed in a Sunday newspaper. The work was well and correctly done and the subject was interesting to the public. I do not doubt that the medical editor of the paper thought that he was doing me a kindness, but that review cost me many hundreds of dollars, because physicians who were about to refer cases to me thought that it would be just as well to send them elsewhere. I know that this is true because they told me so later. Of course no cases came from the newspaper notice, because cases do not come in that way, as any one of experience can testify.

Reporters have one trick that is very fetching for younger men who recognize the reasons why they should not give interviews on professional subjects. The reporter states that he has just come from the office of a very prominent man, who freely answered all of his questions.

On a par with newspaper advertising is the endorsement of proprietary medical preparations. I have given endorsement to only two such preparations, both of which are very useful in my work and both are nearly as standard as Squibb's chloroform. The effect of these two endorsements, however, has been to bring endless arguments from manufacturers who had preparations that were just as good, and I have been offered valuable stock as an inducement to transfer one of the endorsements. Manufacturers of other preparations have sometimes affixed my name without even asking if I would take stock in exchange for it. I discovered one such case by receiving letters from physicians in different parts of the country, thanking me for the receipt of a reprint pamphlet. No such pamphlet had been sent out by me, and on investigation it was found that an enterprising manufacturer had appended a note to one of my contributions on another subject and was using it for advertising purposes. On calling him to account he said that he thought I wouldn't mind, as I had told his representative that his preparation was a good thing.

Recently a physician of scientific attainments asked me to help him by making observations on the action of a new preparation, and stated that a very responsible firm had kindly offered him laboratory facilities. The subject was well worthy of attention, but after a great amount of painstaking experimentation I handed him in perfectly good faith a series of notes which showed that the material was likely to prove valuable

in some kinds of cases, that it was inert in others, and that it was definitely harmful in cases of malignant neoplasm, some ten or twelve cases of this sort having been excited to rapid development in fourteen days of experimentation. The one exception was a case of cancer of the uterus with ulceration of the vagina, in which the ulceration feature of the case had disappeared under treatment with the preparation in question. I had no suspicion that my notes were likely to be published, and in fact would not have thought that they contained anything that the manufacturers would want to publish, but in a short time a pamphlet appeared containing my statement that I had cured cancer with their product.

The result of this publication must be as follows:

1. Physicians who do not know how testimonials are obtained may do great harm by applying this remedy in cases of malignant disease which would otherwise be curable by operation. Thus the patient is injured.

2. Physicians who know that anything so important as a cancer cure would not be presented in such a light and airy manner look askance at the preparation, on the principle of *falsus in uno, falsus in omnibus*. Thus the manufacturer is injured.

3. Physicians who do not know me judge that any one giving testimonials of that sort is unworthy of confidence. Thus I am injured.

This is the sort of advertising that the County Medical Society would prohibit by a by-law. Advertising, indeed! There is not a physician in America whose reputation can stand against it, and the by-law is superfluous.

Some one will ask why offenders who make one's name serve their own purposes are not prosecuted. To this I can only quote the case of two young men who on graduation from college determined upon different lines of life work. One was to devote himself to the study of astronomy. The other was to devote his time to resenting insults and correcting misapprehensions. Each man became at once fully engaged in his occupation.

PATULA.

"THE WHITE THROAT OF THE LAKE."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: My colleague, Dr. St. Clair Thomson, has forwarded me a cutting from your issue of February 15th, which contains a letter from Dr. Charles Greene Cumston, commenting on my description of septic tonsillitis which appeared in *The Lancet* of December 14th. I was not aware that my letter had been noticed in your valuable journal. In my original article, I did not say "at Geneva this form of tonsillitis is termed 'white throat of the lake,'" but "on the Lake of Geneva the disease receives the euphonious title of 'white throat of the Lake.'" Now the Lake of Geneva is forty miles long, and while Geneva is at its western extremity, the cases on which my information is based occurred at Montreux, near the eastern extremity, and under the peculiar conditions of hotel life. I, moreover, mentioned that "the disease is more liable to affect newcomers to an infected district than residents," a point which Dr. Cumston's eight years' experience at Geneva tends to confirm. I am not cognizant of any classical description of the disease and it was for that reason I thought it desirable to draw attention to it as a "specific disease." It would be called "diphthérie" in French, a term which includes an indefinite variety of diseases.

I think it is probably the disease described by the late Sir Morell Mackenzie as "angina ulcerosa" and referred to by Schech in his work on the mouth, throat, and nose.¹ The malady derives importance

¹ P. 101 of Blackie's Translation.

from its etiological association with overcrowding and bad sanitation, and from the fact that the same disease receives a different name in each district where it prevails.

My acquaintance with the disease was first acquired during the three years I practised at Montreux after taking the Swiss federal diploma in medicine at Geneva in 1889. I meet with it yearly in the Engadine and have met with several cases in my practice here.

STUART TIDEY, M.D. LOND., M.R.C.P. LOND.

FLORENCE, March 10, 1896.

THE TRANSVAAL GOVERNMENT MEDICAL BOARD AND AMERICAN MEDICAL DEGREES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: By the advice of an American medical gentleman I apply to you in order to obtain information, and beg of you, in case you cannot yourself give the desired details, to forward this letter to such person or body as you think will be able to oblige me.

The Transvaal Government Medical Board, of which I am the chairman, does not examine for nor grant diplomas in medicine or surgery, but only examines into and decides on the merits of diplomas of such medical men as wish to be registered in this State for the practice of their profession. The rule we follow here is: We accept and admit all diplomas which entitle the legitimate holders to practise in the whole of the country where such diploma has been issued and obtained, and for which a minimum of four years' purely professional medical study is required.

We are constantly receiving applications from holders of various diplomas issued in the different United States of America, and we find a difficulty in deciding on their merits, as the only definite information which we can get here is from two books—(1) "Medical Education and Regulation of Practice of Medicine in United States and Canada," 1884, and (2) "The Medical and Surgical Register of the United States," 1893, third edition. We frequently have applicants for registration with diplomas from universities or colleges which are not specified or detailed in either of these books, and cannot judge as to the value or merits of such diplomas, and my object in writing is to find out whether you can inform us:

(1) Are there State universities or colleges whose degrees are recognized as giving the right to practise throughout the whole of the United States of America?

(2) Can we obtain a list of universities or colleges which demand a four years' course, and can the approximate date be given when such four years' course became compulsory in such college?

(3) Is there a list of the universities and colleges whose degrees are recognized by the medical board of the United States of America?

(4) Are there registers of the qualified men in each State, or is there a general register for the whole of the United States of America on which the name of every qualified man can be found?

Any information you can give us will be most thankfully and gratefully received, for, while we wish to do justice to our State, we also wish to do justice to all duly qualified American doctors who desire to settle in this country.

With an apology for the trouble I am putting you to, I remain,

GORDON MESSUM, M.D.,
Chairman Medical Board.

PRETORIA, SOUTH AFRICAN REPUBLIC,
February 27, 1896.

[In answer to the foregoing questions we beg leave to make the following general statements: There is no general medical registration law for the United States similar to the one in Great Britain, and consequently no governmental register. Each State has or has not its own regulation for medical license and its own system of registration. Medical men removing from one State to the other conform to said laws accordingly. The requirements for license differ in different States, as do also those for graduation in medicine. The report of the Illinois State Board of Health ("Medical Education and Regulation of Practice of Medicine in United States and Canada") is ample authority on all questions concerning medical qualifications and college regulations. It is the nearest approach to an official register that is possible under the existing circumstances of conflicting State interests in medical education and medical legislation. Hence colleges not mentioned in said report are open to the suspicion of being irregular.

With the exception of Maine, Massachusetts, and New Hampshire, all the other States insist either on an official registration of medical diplomas or an independent State examination for license. In the former class, in which such examinations are not obligatory, are: California, Colorado, Connecticut, Delaware, Illinois, Iowa, Kentucky, Missouri, Montana, New Mexico, Ohio, Oklahoma, Oregon, Tennessee, West Virginia, and Vermont. In the latter class, in which State examinations are necessary before any license for practice can be obtained, are: Alabama, Arkansas, Florida, Maryland, Minnesota, Mississippi, New Jersey, New York, North Carolina, North Dakota, South Dakota, Texas, Utah, Virginia, Washington, and portions of Indian Territory.

All the medical colleges in the State of New York are now required by law to have a four years' course of instruction. The colleges in other States having equal terms of study are: The medical departments of the University of Pennsylvania, of the Harvard University, of the University of Michigan, of the Northwestern University, Illinois; of the Central Tennessee College, of the Leonard Medical School of North Carolina, and of the Johns Hopkins University of Baltimore.

With possibly one or two exceptions recently made but not officially announced, all the other colleges require but three courses of lectures averaging from five to nine months each.—ED.]

Nervous Œdema.—Fedorovsky (*Pratch*, No. 26, 1895) relates the case of a soldier who was injured severely and after a period of unconsciousness found in addition to a paralysis that there was a unilateral œdema of the face. Since this time the patient has had frequent headaches and œdema of the cheek and eyelid, all upon the left side. The œdema can be brought on by energetic bodily movements, rapid walking, etc., and lasts two days. There is slight exaggeration of reflexes, and there are no stigmata of hysteria. The author attributes the condition to a neurosis of traumatic origin which has provoked a special excitability of the vasomotor nerves of the face.

Gastric Ulcer.—Dr. Mettler says a dull, lancinating, burning, and gnawing pain, strictly localized near the epigastrium, shooting through to the back and appearing with peculiar distinctness near the angle of the left scapula, occurring at times in severe paroxysms, increased by food and external pressure, and somewhat modified by posture, is almost pathognomonic of gastric ulcer.

Therapeutic Hints.

Gout.—Dr. Noorden has concluded that the gouty condition is independent of the presence of uric acid in the blood; the tissue necrosis he ascribes to the activity of a hypothetical ferment and he believes the uric acid deposited locally is formed at the necrosed focus.

Intermittent Treatment of Syphilis.—In the first year of the treatment mercury should be given for six months and potassium iodide for three months, with a pause of three months; for the second or third years, for from two to five months, mixed treatment; for the third and fourth years sulphur baths.—FOURNIER.

Chronic Nephritis.—

R Nitroglycerin..... gr. $\frac{1}{100}$
Tr. digitalis..... ℥ ij.
Tr. strophanthus..... ℥ ij.
Tr. belladonna..... ℥ ss.
To be used in cases marked by high arterial tension.

—DA COSTA.

Eczema.—

R Zinci oxid..... 20
Pulv. acidi borici..... 10
Bismuthi subnit..... 5
Ol. olivæ..... 55
S. Externally, especially in particularly rebellious eruptions.

—La Sem. Médicale.

Lumbago.—

R Sodium salicylate..... ʒ ss.
Potassium iodide..... ij.
Compound syrup of sarsaparilla..... iss.
Water..... q. s. ad ʒ iij.
M. S. A teaspoonful in water thrice daily, after meals.

—SOLIS-COHEN.

Cough Mixture Without Opium.—

R Dilute hydrobromic acid,
Spirits of chloroform..... āā ʒ i.
Syrup of wild cherry and mucilage to make..... ʒ iss.
M. S. Teaspoonful as required.

—Practitioner.

Amygdalitis.—Dr. Fox (*Lancet*) speaks favorably of the local application of a strong solution of cocaine as a means of aborting this symptom of disease.

Pruriginous Dermatoses.—Dr. Brocq uses the following:

R Talci,
Amyl. pur. āā 50
Glycerini..... 20
Liq. plumbi subacet. dilut..... 100

Shake the bottle thoroughly. Add to a small quantity of the contents double the quantity of water and apply to the affected parts with a soft paint brush. This leaves a dry layer of powder, which exercises a cooling, antipruriginous, astringent, and antiseptic action.

Otitis Externa or Media.—

R Water..... 60
Laudanum..... 4 to 8
Boric acid..... 2

Pour into the ear a teaspoonful of this mixture as hot as can be borne. Allow it to remain ten or fifteen minutes. To empty it out, let the patient cover the ear with a handkerchief and bend the head toward the side with gentle shaking. Repeat if necessary.

MENIERE, *Lancet*.

Biliary Colic—Dr. Turnbull (*Lancet*) uses tablets of one one-hundredth of a grain of nitroglycerin with success. He was induced to use this drug from its known power of relaxing unstriated muscle fibres.

When there is an intolerance for morphine it would be well to try this drug.

Periodic Headache.—

R Fluid ext. ergot..... ʒ i.
Elix. quinine..... ʒ iij.

—DR. LUIGI CAPPELLARI, *La Riforma Medica*, No. 241, p. 191.

Diphtheria.—Dr. Seibert dips absorbent cotton attached to a holder into a solution of peroxide of hydrogen and applies it gently to the false membrane with a rotary movement and slight friction. Frequent changes of the cotton and hydrogen are deemed advisable. Patience, time, and frequent applications gradually remove the entire false membrane. He then applies in a similar manner the following lotion:

R Tr. ferri chloridi..... ʒ i.
Alcohol vel listerin..... ʒ i.
Hydrarg. bichloridi..... gr. ij.
Menthol..... ʒ i.

Whooping Cough.—Dr. Hughes (*Medical Times and Hospital Gazette*) suggests the following:

R Codein. sulphat..... gr. i.
Acid. carbolic pur..... gr. viij.
Syrup. limonis,
Syrup. simp..... āā ʒ ss.
Glycerini pur..... ʒ i.
S. A teaspoonful every two or three hours.

Cough Mixture.—

R Acid. hydrocyan. dil..... ʒ ss.
Acid. nitric. dil..... ʒ iij.
Glycerini..... ʒ i.
Inf. quassiae..... ad ʒ viij.
Ft. mist. S. A tablespoonful in a wineglass of water three times a day.

It is both a sedative and tonic in cases of phthisis. —WARBURTON BEGBIE, *Pharmacopæia of the Edinburgh Royal Infirmary*.

To Abort a Cold.—

R Sodii salicylat..... ʒ ij.
Spirit. ammon. aromat..... ʒ i.
Syrup. aurantii..... ad ʒ ij.
S. One teaspoonful every four hours.

—Practitioner.

Goitre.—Dr. Galle uses parenchymatous injection of one-quarter to one drachm of the following:

R Iodoform..... 1 part.
Sulphuric ether,
Olive oil..... āā 7 parts.

—*Medical Times and Hospital Gazette*.

A New Pomade.—Dr. Müller, of Berlin, has just given in the *Deutsche Medicinal-Zeitung*, No. 6, the formula which follows as the very best where mercurial frictions are required, since it is very soft, has scarcely any odor, and penetrates readily into the tissues without irritating the skin.

R Metallic mercury..... 33.3
Wool fat..... 44.7
American vaseline..... 12
Neutral potash soap (prepared with olive oil)... 10

Blepharitis.—

R Red oxide of mercury..... gr. x.
Vaseline..... ʒ ss.
M. S. Apply to the edge of the lids at bedtime.

Blepharitis Ciliaris.—

R Neutral acetate of lead..... 0.10
Hydrochlorate of cocaine..... 0.15
White vaseline..... 3
M. S. Make frequent applications along the margins of the lids.

—LANDOLT et GYGAX.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 6, 1896.

ANDREW H. SMITH, M.D., PRESIDENT, IN THE CHAIR.

Nephritis with Eye Symptoms.—DR. BEVERLY ROBINSON presented a young man whom he had treated for nephritis and in whom Dr. Charles S. Bull had found on ophthalmoscopic examination albuminuric retinitis. The patient was a trainman by occupation, twenty-two years of age, who had had measles in childhood, and malaria nine years ago. There was no history of rheumatic, cardiac, hepatic, or pulmonary disease. He was moderate in the use of alcoholic liquors. His father had died of Bright's disease.

A year ago the patient began to have pain in the lumbar region; ten weeks ago he was attacked by swelling of the hands and legs, which was worst in the morning; six weeks before he had blurring of the eyes, but was able to see correctly; a similar blurring occurred ten days ago and again a week before admission to the hospital, December 19, 1895. Since the last attack the eyesight had been impaired, and he was unable to recognize people unless very near to them. He had headache off and on; the urine had recently increased. The appetite was good, the bowels were constipated, the skin was pallid, and the mucous membranes were well nourished. The impulse at the heart apex in the fifth intercostal space, just outside the nipple line, was rather forcible, and the action regular. A short blowing systolic murmur, not transmitted, was heard over the mitral area. The second aortic sound was somewhat accentuated. The pulse was regular, of good force and marked tension. Examination of eyes revealed neuro-retinitis with hemorrhage.

The urine contained from five to twenty-five per cent. of albumin and some granular casts; its specific gravity was low, 1.008. Dr. Robinson said the case was of interest from two points of view. First, with regard to treatment, it was known that in many cases of nephritis the best possible results came from nitroglycerin. Some patients bore the drug in considerable quantity for a time with benefit, but he did not think it was generally known to what extent its use could be pushed without producing unpleasant effects or apparently more than slight physiological effects. At one time this patient had been given over one hundred grains of pure nitroglycerin in alcoholic solution in twenty-four hours without causing any known poisonous effects. It seemed to reduce the tension of the pulse, but no other appreciable effect was noticed. Apparently it did not influence the urine one way or another. The nitroglycerin was said by the chemist to be pure, and when tried on patients sensitive to it the usual effects were produced.

The other point of interest related to the eyes, and in this connection he read the following letter from Dr. Charles Stedman Bull: "J. M.— came under my observation for the first time December 16, 1895, with a complaint of failing vision for six weeks. His vision was $\frac{7}{30}$ in each eye (type No. 200 read at seven feet), and there were the usual signs of neuro-retinitis nephritica with patches of yellow exudation and hemorrhages. There was albumin, twenty-five per cent., and hyaline and granular casts. On January 3, 1896, the vision was, in the right eye, $\frac{2}{30}$, and in the left eye, $\frac{2}{30}$ with the correction of hypermetropia and astigmatism. The general retinal edema was very much lessened; there were no new patches of exudation and no new hemorrhages. To-day, February 7th, the vision in each eye is $\frac{2}{10}$ and he reads Jaeger

No. 2, very small type, at the usual distance. The fundus is about the same. There is no new exudation, and but very little absorption of the patches already existing."

A second letter from Dr. Bull, dated February 11th, read as follows: "In the case of J. M.— it cannot be said that the improvement in vision actually corresponds to the ophthalmoscopic change in the fundus. When these cases of exudative neuro-retinitis in patients with chronic renal disease are subjected to proper treatment of the renal disease, the vision always improves and is often restored to normal, while the exudation in the retina remains. The improvement in J. M.—'s vision is due to the rapid and marked disappearance of the general edema of the retina, which has been unusually rapid in his case. The fatty exudation in the region of the macula and around the optic disc remains about the same. This exudation seldom disappears and its presence is compatible with very useful vision. Most of these patients, however, do not live very long; the majority of them die within the first year after the appearance of the retinitis. It is possible to have very extensive fatty exudation in the retina coexisting with good vision."

Dr. Robinson added that he thought the prognosis with regard to death depended very much upon how the patients were treated. If their circumstances in life were such as to enable them to choose the best climate and have the best surroundings, in addition to getting proper medical care, they might live for years. He had had patients with albuminuria and all evidences of chronic nephritis so pronounced that at times he felt life was in imminent danger, yet they had lived for years and always seemed to be in as good condition as when he had first seen them. He asked for the experience of members with regard to the prognosis of chronic Bright's disease and the other points mentioned. He also questioned whether patients with chronic Bright's disease did not acquire a sort of physiological resistance to nitroglycerin, similar, for instance, to that shown to antimony by patients with pneumonia.

DR. C. S. BULL said that twelve years ago he read a paper before the Ophthalmological Society in London, based on the examination of over one hundred and forty cases of retinitis albuminurica, and the very unexpected deduction which he was compelled to draw was that the large majority of patients, about sixty-eight per cent., die within a year after the appearance of ocular symptoms; and that of the sixty-eight per cent. seventy-five per cent. die within six months. It was a well-known fact that in neuro-retinitis albuminurica marked improvement in vision might take place after disappearance of the general edema of the retina, while the hemorrhagic spots remained. He had had a lady under observation for seventeen years with marked retinitis albuminurica, in whose eyes the patches were as distinct then as when he first examined her, yet her vision was nearly normal. But, of course, if there were recurring hemorrhages they deteriorated the vision, and that deterioration was not recovered from. Since the appearance of his paper three others had been published by foreign confrères, all of whom drew the same conclusion, that most patients with nephritis lived but a short time after the appearance of retinitis. A parallel case of good vision persisting in serious involvement of the eye was seen in many cases of choked disc, provided the papillitis was not due to rapidly growing intracranial tumor. Of course there was a limited field in which there was no vision.

DR. GEORGE L. PEABODY had occasionally encountered patients whose arterial tension was not diminished by even very large doses of nitroglycerin. He had never given as much as ten grains at a dose, the amount Dr. Robinson had at one time given his pa-

tient, but he had gradually increased to two grains without noticing marked physiological effect or change in the pulse tension. He recalled the case of a patient who had suffered periodically from attacks of renal vomiting, the vomiting persisting for days. Nothing relieved him except enormous doses of morphine given subcutaneously. Nitroglycerin had no effect on the high tension of the pulse, whereas chloral hydrate had. In giving chloral hydrate he began with five grains every three hours and increased to ten grains every three hours, giving often as much as eighty grains in twenty-four hours. There was no doubt that many people were not affected by nitroglycerin and in them chloral hydrate usually acted admirably, fulfilling the double purpose of relaxing arterial tension and producing sleep at night.

Regarding the duration of life, he thought one must consider the kind of nephritis. If it were distinctly a parenchymatous nephritis, with a large quantity of albumin in scanty urine, the prognosis was much worse than if it were an interstitial nephritis with abundant urine and few casts. He had a patient in high official position who for years had had chronic Bright's disease, who always had some α -edema, whose urine always contained some albumin and casts, yet who was able to attend to his official duties without much difficulty. But this patient took care of himself, living chiefly on milk, and on milk alone during exacerbation of symptoms. But patients who had pronounced symptoms in the way of α -edema and scanty urine were in his judgment patients in whom the prognosis was much worse, although more could be done for them in the way of climate, probably, than for those having interstitial nephritis.

THE PRESIDENT asked Dr. Peabody whether he thought eye complications rendered the prognosis bad.

DR. PEABODY thought they did. Pronounced eye symptoms always impressed him with the gravity of the prognosis. A gentleman well known to the local profession, while in apparently perfect health, felt that he needed a change of glasses and went to Dr. Noyes. Dr. Noyes dilated his pupils and discovered at the one sitting retinal changes of nephritic origin, and gave a gloomy prognosis. Notwithstanding the fact that the man was in good health, he immediately gave up his duties and went abroad, but died in the course of two or three months of urinary suppression and coma.

Diphtheritic Palsies and the Use of Antitoxin.—DR. CHARLES L. DANA read the paper (see page 513).

Palsy Not Produced by Antitoxin.—DR. HERMAN M. BIGGS said, as to the possibility of the production of palsy by antitoxin, that he thought it was quite out of the question, for out of the very large number of cases in which it had been used for immunizing purposes it had produced no such result in any. It had been used in New York institutions for immunization in at least fifteen hundred cases and had never caused paralysis. The fact that in cases of diphtheria treated by antitoxin the palsies were not very much reduced in number was easily explained. Rarely was a case treated early enough with antitoxin for it to counteract absolutely all of the diphtheria toxin. More or less toxæmia always occurred before the treatment was begun, enough to produce nerve degeneration. Sidney Martin had shown by experimental work that nerve degeneration was often present in animals which had received only a small dose of toxin, not enough to produce death or even symptoms before paralysis. Again, there was the fact referred to by Dr. Dana, that a larger percentage of cases of diphtheria recovered under antitoxin treatment than without it, and consequently there was a larger percentage of the total number of all cases of diphtheria in which it was possible for paralysis to

make its appearance. But the essential point was the one just mentioned, that there was a certain amount of toxæmia before the antitoxin was administered, a sufficient amount to produce the nerve degeneration. The fact that palsies did occur seemed to him not in the slightest degree an indictment of the antitoxin treatment.

DR. BEVERLY ROBINSON thought Dr. Biggs' reasoning was somewhat faulty. According to his observation diphtheritic paralysis was often seen in cases in which the diphtheria at the beginning of the attack had not been very severe, but in which the entire duration had been rather long. The inference was that but little toxæmia had occurred the first few days, and if antitoxin were used it ought, in these mild cases at least, to reduce the percentage of cases of paralysis.

DR. LAMBERT, invited guest, thought the following facts should be taken into consideration: It required a certain amount of antitoxin to counteract a given amount of diphtheritic toxin circulating in the blood; the exact amount of toxin present in a given case was not known; new toxin was constantly being added, and the antitoxin must be sufficient to counteract this also; antitoxin was not retroactive, and could not repair injury already done by the toxin. Anent Dr. Robinson's remarks, one could not say that a sufficient quantity of the toxin had not been absorbed at a given time to produce serious changes, such as might lead to paralysis. It was one of the peculiarities of diphtheria that the early symptoms might be mild, while the late manifestations might be severe.

DR. W. H. PARKER, invited guest, said it was interesting to watch the effects of antitoxin on guinea-pigs used for test purposes in the laboratory connected with the hospital for patients with diphtheria. Some of the animals received enough of the diphtheria toxin to produce death, others an amount not quite sufficient to produce that result. A certain number of the latter developed diphtheritic paralysis later. Of the animals injected with the toxin and treated with antitoxin, some were given enough antitoxin to prevent manifestations of the toxin, and none of these developed paralysis; others which received a less amount recovered, but some showed paralytic symptoms; still others received an amount not sufficient to prevent death. One who had watched the guinea-pigs could hardly see how it was possible that the antitoxin could produce paralysis; on the contrary, it seemed to prevent it by counteracting the diphtheritic toxin. The larger the amount of antitoxin administered, the less apt was there to be paralysis, and when a certain amount was passed paralysis never developed.

Regarding the frequency of paralysis in the Willard Parker Hospital, it was his custom to go in from the laboratory every day to see how the cases were getting along. There was no doubt that there had been rather more paralysis there since the introduction of antitoxin than before, but, as Dr. Dana had also said, this occurred to a considerable extent in patients who without antitoxin treatment would have died of the diphtheria before paralysis could show itself. A good many children brought there had diphtheria in severe form, the nose completely blocked with membrane which it was almost impossible to dislodge. Formerly it was very rare for this class of patients to recover, but under antitoxin treatment nearly all either recovered completely or recovered temporarily, and then after two or three weeks they might develop either general paralysis or local paralysis of muscles of the pharynx and deglutition. Some died of the paralysis, but many of them got well. Again, patients came in at different stages of the diphtheria—the second, third, fourth, seventh day—and some had even developed paralysis on the day of admission or the day following. Of course, antitoxin could have little influence in pre-

venting paralysis in late cases. It seemed to him that the frequency of paralysis was proportionate to the severity of the diphtheria when the patients entered the hospital and were put under antitoxin treatment.

Value of a Bacteriological Diagnosis.—DR. ROBINSON said that he would like to hear from Dr. Park a word as to diagnosis based on bacteriological examination. In one case he was very much alarmed lest a certain patient, a boy, had diphtheria, and was decidedly relieved when Dr. Park reported from bacteriological examination that it was not diphtheria. In another instance a lady had all the clinical evidences of diphtheria, and he was again gratified to learn from the bacteriologist that it was not diphtheria. On the other hand, he had attended two cases in which neither he nor members of the family thought the patients were very sick, yet bacteriological examination of the mucus showed diphtheria. In a certain hospital free from diphtheria it was reported that a number of the children had the Loeffler bacillus in the throat. In view of facts like these, he believed the profession was more or less in a quandary at the present time regarding a bacteriological diagnosis.

DR. PARK rejoined that if the culture from the throat was properly made and did not show bacilli of diphtheria, it could be safely assumed that the case was not one of diphtheria and was not liable to transfer that disease. Now and then a culture was taken from a limited part of the throat and did not show diphtheria bacilli, while cultures from another part did show them, and the possibility of this occurrence left a shadow of doubt.

Regarding light cases of diphtheria in which bacteria were found, he thought it was a difficult question to decide practically how to manage them. As a rule the more virulent the bacilli the more malignant was the disease, but in some of the severest cases of tonsillitis the Loeffler bacillus was absent. Recently the health department had followed up thirty cases reported as diphtheria of the tonsil, but in twenty-seven of them it had found the cultures were not virulent when inoculated into animals. Three were virulent, and in only two of the thirty cases did they find that the disease had been transmitted to others. As a rule, the less virulent cases were less likely to transmit the disease.

He concluded by saying that when the bacilli of diphtheria were not found the case was not one of diphtheria; but when they were found, such cases need not be more severe than the others, yet they could transmit diphtheria.

DR. PEABODY asked whether the health department still considered it necessary to isolate patients so long as Loeffler bacilli were found.

DR. PARK replied that a new regulation of the health department, which had not yet been put into effect, left it to the judgment of the attending physician whether in private houses patients who were convalescent should continue to be isolated. But it was expected that the physician would explain to the family the possible dangers. If he would make that explanation, the health department would allow him to assume the responsibility and would not enforce isolation. Children from that house would not be allowed to go to school.

DR. PEABODY asked how long he had known bacilli to remain in the throat after convalescence.

DR. PARK replied that nearly all disappeared within two or three weeks, but now and then some remained two or three months, and in two cases they were present nearly nine months. In the latter it was possible that reinfection had taken place, but he thought not.

Unreliability of Anatomical Diagnosis.—DR. BIGGS thought one of the great difficulties of practitioners was the fact that they had not ceased to depend upon

an anatomical diagnosis. So far as the mucous membrane was concerned there was absolutely nothing which was pathognomonic of diphtheria. In diphtheria the membrane might be simply on the surface, or it might involve the substance of the tissue and be associated with enlarged lymphatics. There was no anatomical diphtheritic inflammation which was characteristic of inflammation produced solely by diphtheria bacilli. The disease diphtheria was such an inflammation as was produced by diphtheria bacilli and by those bacilli only. Of the patients in whom diphtheria bacilli were not present, practically all recovered except the very young; whereas, if diphtheria bacilli were present, it did not matter how mild the case might seem to be, we could not say until the termination of the disease that the patient would recover. The child of a wealthy family had mild tonsillitis while on the ocean. On arrival at port they visited some friends, and within forty-eight hours one of the children in the family visited came down with diphtheria and soon died. The throat of the visiting child was then examined and most virulent diphtheria bacilli were found, yet they had caused little disturbance in this patient, but had rapidly produced death when transferred to the other child.

In private houses there was so much less likelihood of disseminating the disease that the health department had concluded to introduce the regulation mentioned by Dr. Park, to be put into effect shortly, leaving the question of isolation after convalescence with the attending physician. But this regulation would not apply to boarding-houses, tenements, etc.

DR. PEABODY remarked that it was almost impossible in many instances for the physician not to take that responsibility. He had seen a governess who had membrane in her throat; he told her he could not say for twenty-four hours whether she had diphtheria or not, but gave antitoxin. It was shown in twenty-four hours that there were no Loeffler bacilli in her throat. She was in attendance on four children and he took cultures from their throats. Loeffler bacilli were present in two of them, and remained present so long as examinations were made throughout the winter, yet the children presented absolutely no symptoms.

DR. LAMBERT remarked that it had been found that the serum of the blood of children possessed a certain amount of immunizing power against diphtheria toxin, which would account to some extent for some of the facts mentioned. He knew of two nurses who had sore throat; in one it was quite severe, in the other light. In both diphtheria bacilli were present; under antitoxin they all disappeared within ten days in the severe case, while in the other they were still present.

DR. PARK thought that the severe cases usually got well more rapidly, if they recovered at all, while the mild ones lingered. In reply to an interrogatory by DR. PEABODY as to how long antitoxin retained its strength, he said he would prefer to change for a new sample after six months. By that time it had lost part of its strength.

Books.—Drs. Du Cazal and Catrin (*L'Union Médicale*, 1., p. 608) from personally conducted experiments conclude: 1. New books, without being aseptic, do not contain pathogenic microbes. 2. Books of hospital libraries may transmit Klebs-Loeffler bacillus, the streptococcus, and the pneumococcus, but Koch's bacillus cannot be transmitted in this manner. 3. Only unbound books should be placed in the hands of patients, and these should be repeatedly sterilized.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 2, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR,

The Clinical Aspects of Glycosuria.—DR. WILLIAM H. DRAPER read a paper on glycosuria, chiefly from a clinical aspect. Clinically glycosuria, like albuminuria, was a symptom. As albuminuria did not always or necessarily point to a renal lesion, but often presented itself as a transient, intermittent, or persistent elimination, associated with a variety of functional or organic derangements, so the presence of sugar in the urine was a symptom of varying significance. Glycosuria was a consequence of lithæmia, and lithæmia would have the advantage of diabetes mellitus as the name of the disease. This same process directed attention to the state of the blood, which was still imperfectly understood. Chemistry and experimental physiology had taught us how to explain many symptoms, to estimate the degrees of its severity, to measure its progress, and to forecast its consequences. It could not be said they had rendered us much assistance in therapeutics, although they had made plain the reason why the treatment, which was empirical in its origin, was rational in its principle, and especially why diet failed to do good in the graver forms of the disease.

Often a purely accidental circumstance revealed the true nature of the patient's complaint. There was no better illustration of this statement than the fact that a considerable number of diabetics had their disease revealed to them by specialists. One fell into the hands of an oculist for amblyopia or commencing cataract; another sought advice from a dermatologist for troublesome pruritus or eczema; another went to the dentist because his teeth were decayed; another consulted a specialist because of dyspepsia or constipation, another a neurologist for an obstinate neuralgia or nervous prostration. While the symptom complex varied, yet glycosuria was sometimes unaccompanied by any serious derangement of the health. This might be true even in cases known to be associated with lesions of the nervous centres or of the viscera, but in cases with or without serious symptoms there might be no demonstrable lesion.

Clinically, we recognized two varieties of glycosuria. One was that in which it was apparently the result of imperfect combustion of carbohydrates, and in which the withdrawal of these caused the disappearance of sugar from the urine. The second variety was that in which the glycosuria continued in spite of the complete withdrawal of carbohydrates. The first form was often mild, intermittent, and always more or less controllable; the second was the opposite.

That glycosuria had an intimate connection with liver glycogenesis was still an accepted opinion, but one which had always had an opponent in Pavy who continued to maintain that the liver was a sugar-destroying and not a sugar-forming organ. He admitted the glycogenetic function of the liver, but denied that it was the source of sugar in the blood.

From a chemical point of view glycosuria was a disease of suboxidation of the elements of our food, nitrogenous as well as non-nitrogenous. The causes of this suboxidation were still obscure. Whether it was the result of disordered function of one organ or of several, whether of the liver or of the nervous centres, etc., was a question not yet satisfactorily solved. Clinical observation was of interest in pointing to some of the predisposing causes. In a number of cases the disease seemed to have its origin in inherited constitutional abnormality of nutrition. It might descend to the third and fourth generation. While the proportion of cases in which direct heredity could

be traced was small, it was different if we considered the question of indirect heredity. By this he meant the inherited constitutional incapacity for the easy and rapid digestion of carbohydrates, tending to the production of glycosuria. It was now generally admitted by clinicians that lithæmic gout was a congener of glycosuria. In the light of such relationship, heredity would be seen to play a much larger rôle in the causation of diabetes. The number of cases with a gouty ancestry was considerable. Dr. Draper could say from personal observation that a gouty subject, if he should become glycosuric, would cease to have attacks of gout as long as the glycosuria lasted, but when it ceased he was very apt to have recurrence of gout. The favorable influence of glycosuria on gout and gravel was probably due to free elimination of uric acid with the increased secretion of saccharine urine in diabetes.

After heredity was the incapacity for the digestion of carbohydrates. This was aggravated by over-indulgence or neglect to adapt one's diet to habits of life and occupation. The majority of cases of glycosuria were seen in peoples who ate most of farinaceous foods. It was common in India, for example. It had been stated that there was a special disposition to diabetes among Hebrews and Dr. Draper's observation would seem to confirm this statement, and it might be explained by the fact that in western countries the Hebrews were not an agricultural people, but were engaged in indoor occupations favorable to imperfect metabolism of food. Most cases occurred between thirty and sixty. Absence in infancy and adolescence was probably due to activity of digestion in early life. The youngest case which he had seen was in a child under one year. It was much more common in men than in women, for which no direct cause could be assigned, unless men were given more to debauchery, excessive eating and drinking, and were more exposed to traumatism. Excessive muscular exertion had been regarded as a cause, but in Dr. Draper's experience this was rare. The same was true of paludal poisoning. He thought the malarial organism could act only through depressing and deranging the nutritive processes. Cases following moral and emotional shock, cerebral tumors, etc., had been seen by all who had had much experience with diabetes.

As illustrating the tendency of mild cases to become severe, he had seen three brothers, all of whom had a little sugar in the urine, but were able to attend to large business interests for a long period. The disease gradually merged into the severe form; two of the patients had gout at intervals; one, who died of diabetes, had eleven stones in the bladder. In the mild form the amount of sugar passed did not usually exceed an ounce or two in twenty-four hours. Severe cases had been known to pass from one to seven gallons of urine, containing twenty to forty ounces of sugar in a day. It had been estimated that this could be made to lift a million pounds one foot.

As mild cases progressed, we observed symptoms connected with tissue waste, loss of strength and energy, incapacity to evolve force of any kind; there was plenty of fuel, but no fire. The fuel circulated and left the body unconsumed. There was unappeased thirst and appetite.

Among the accompaniments which accounted for the sufferings of the patients were neuralgias and paræsthesia, sciatica, burning sensation in palms and soles, pruritus, independent of and including that of the genitals. In persistent neuralgias, especially of sciatic distribution, the importance of examining the urine was not sufficiently appreciated. It seemed reasonable to suppose that many of these were the result of peripheral nerve lesion.

Another accompaniment was albuminuria. This

was generally slight, but sometimes was considerable, especially when it alternated with the glycosuria. The two might exist in this way for a long period and permit of a fair degree of health. Another curious fact was the frequent association of diabetes with obesity. It was less apt to be attended with severe symptoms than in thin subjects. One of the most painful symptoms, and one most difficult to overcome, was constipation. Rapidly fatal glycosuria occurring after traumatism, mental shock, etc., was, he thought, usually an aggravation of a previously existing mild form which perhaps had not been discovered. In grave forms the circulation of unconsumed sugar tended to the production of local congestions, imperfect nutrition, gangrene, etc.

Prognosis.—The question of prognosis was a difficult one. The simple form had a good prognosis so long as the patient was under control, but when the amount of sugar and urine increased out of proportion to the food and drink, the prognosis became unfavorable. The prognosis in traumatic cases was sometimes good, sometimes bad. He had recently had two such cases—one recovered, the other died.

Therapeutics.—So far as rational therapeutics went, it was summed up in dietetic management. Further than this we had only empiricism based on the theory of the origin of the disease to guide us. The non-combustion of carbohydrates was probably the starting-point in all cases. Two measures had thus suggested themselves: one was the withdrawal of carbohydrates from the diet; the other, to quicken their transformation. No drug yet discovered appeared to answer the second indication, although time would fail to make a list of the medicines which had been vaunted for it. They had all been used in connection with restricted diet, and often the benefit had probably been due to the latter. Iron and alkalies undoubtedly had the power to promote oxidation in the living body, and it was interesting to note that they were as valuable in lithæmia as in glycosuria. But they required to be accompanied by restricted diet. His own experience would go to show that it was in the cases of gouty habit that the alkalies did most good. The inhalation of oxygen and enforced exercise with a view to stimulating oxidation, had failed. One who had seen much of diabetes knew how valuable was opium. There was little question that opium in some form, in combination with alkalies, constituted the best method of controlling the sufferings of the patient if not the progress of his disease. He had not time to go into the details of the dietetic treatment. Essentially it converted the individual from an omnivorous into a carnivorous animal, and with the art of cooking this could be accomplished with less discomfort than one would naturally suppose.

The Mystery of Diabetes Growing More Impenetrable.—DR. WILLIAM H. THOMSON said the subject of diabetes reminded him of the answer of the old colored woman when asked what books she liked best. She liked the Book of Revelation best, because it was so easy to understand. When the glycogenic function of the liver was discovered, physiologists thought it would throw new light upon diabetes, but the many years spent since then in physiological and pathological experimentation had, while adding many new facts, only deepened the mystery. After reading Pavy's papers he had begun to think that Claude Bernard had started us on a wrong scent. He was sure that if derangement of the liver had anything to do with diabetes it would be very difficult to say what that derangement must be. It was not seen in hyperæmia, acute or chronic; the liver was deranged in various ways in the production of jaundice, yet there was no diabetes; it might be invaded by a neoplasm, but diabetes would not be found; in extreme cirrhosis its

functions might be almost or entirely abolished, still there was no indication that the carbohydrates were not being properly disposed of in the body. Of course in any of these conditions there might be sporadic glycosuria, but there was no causative relation. On the other hand, the attention of the profession had been forcibly directed the past ten years to lesions of the pancreas in connection with diabetes. First, we heard that extirpation of the pancreas invariably produced diabetes, which proceeded to a fatal issue in dogs. Therefore it was supposed that the pancreatic secretion must have some important action in the conversion of carbohydrates. But further observation showed that when this fluid was not admitted to the intestine at all, but conducted away by a fistula, there was no diabetes. Further, three-fourths of the gland could be extirpated, yet no diabetes would follow. Even the remaining fourth could be skilfully transferred to another part of the body without becoming atrophied, and still no diabetes would ensue. But as soon as this remaining fourth was cut off, diabetes set in at once. As had been stated, this fact opened up a new field, to the effect that every gland in the body apparently had a great deal to do with the economy aside from its secretion. It had been shown that the relation of the pancreas to diabetes was not through the pancreatic juice, but through a ferment generated by a certain set of cells. Removal of the testicle produced important changes in the nutrition of the body, as was illustrated by the difference between the ox and the bull. Removal of the pituitary body produced important osseous changes. Myxœdema resulted from atrophy of the thyroid gland. Remove the few cells referred to, and the glycolytic function would be interfered with, causing diabetes.

Dr. Thomson had eleven cases of diabetes in private practice at present, and must say that he knew of no disease in which the histories were more in contrast. It happened that out of the eleven four were women, a larger percentage of females than usual. He thought the prognosis depended more upon the age than upon any other condition. The younger the patient the worse the prognosis. The old man could be told that he would go on to live as long as his fellow-men. In fact diabetes seemed to rejuvenate the old man by counteracting the tendency to hardening of the arteries. In gout, instead of having a compressible pulse, we had an incompressible one, and the conditions were so different that he could not believe the origin could be the same as that in diabetes.

Dr. Thomson's Theory.—Each man, Dr. Thomson said, felt himself at liberty to have a theory in relation to glycosuria. The following was his: Where were the starchy elements of the food burned out? Not in the liver, not in the glands of the body, not in the lungs. It had been shown beyond question that when carbonic acid resulted from burning with oxygen it took place in one tissue alone, and that was in muscle. In other words, the muscles of the body were the furnaces of the body. The muscles had two entirely distinct functions, that of contraction and that of heat-production. All authorities were agreed that diabetes was not a result of power to produce sugar, but of lack of power to use it. Might not the fault, then, lie in disturbance of innervation of the muscles? This theory would explain some of the clinical phenomena, among them that of the danger of allowing these patients to become over fatigued.

Diabetes in Wall Street.—DR. ANDREW H. SMITH, in referring to a nervous influence as the starting-point in many cases of glycosuria, mentioned the case of a man who became suddenly diabetic from severe fright in a runaway accident. Prolonged mental strain of less degree was capable of producing a similar effect, and this would account for the large number

of cases among Wall-Street men. He once had a case of diabetes in a locomotive engineer, who told him that it was extremely common among those of that occupation, and through the medical director of the Brotherhood of Locomotive Engineers he had learned that diabetes occurred about seven times more frequently among members of this organization than among the general public. When asked his explanation, he stated by letter three points: 1, The jar communicated from the cab to the spinal column; 2, alternate heating and cooling of the body; 3, great mental strain. Dr. Smith thought there was probably no other occupation demanding such intensity of attention. All three facts seemed to point to the nervous system as being directly involved.

A Vicious Circle.—Dr. Smith had entertained the theory for some time that the moment sugar began to circulate in the blood it set up a vicious circle, tending to the continuance of the glycosuria by irritating the centre originally disturbed, whether this centre were at the floor of the fourth ventricle, in the glandular structure of the pancreas, or wherever it might be. The influence of heredity was strong. The sons of diabetics were apt to be diabetic, and if the father's position was mentally an arduous one, as that of railroad president, he should not transmit his disease to his son. Like Dr. Thomson, he had found the disease easier to manage in old people; in fact, in them it usually manifested itself, and it was unfortunate for such a patient to fall into the hands of a physician too much wedded to restricted diet. He believed that diabetic coma was not infrequently precipitated by too rigid an exclusion of carbohydrates, especially in the aged.

Fancy Free.—DR. W. GILMAN THOMPSON said he had no new theory, nor did it seem to him that it was necessary or desirable that we should confine ourselves to one theory of diabetes. He had been much interested in what Dr. Draper had said regarding the mutual relation between gout and diabetes, and he had himself lately given as much attention, in the analysis of the urine, to the relation of the uric acid, etc., to the metabolic processes of the body as to the discovery of sugar itself. He believed that indirect heredity did apply to a large proportion of cases, but it would not explain the indigestion of animal food which occurred in many cases in the early manifestations of the disease. Then there were many people who suffered from indigestion of starchy foods in whom diabetes manifested itself at no time. Whatever theory we might adopt, he thought it was a matter of general experience that when diabetes once became inaugurated its progress was very much under the influence of the nervous system. Various strains on the nervous system tended to aggravate it, and it was for this reason he believed opium was so useful. He had tried a large number of remedies, one by one, and had given them up, and now relied chiefly on alkalies and opium, aside from dietetics. He had not found codeine as useful as opium. Regarding diet, he divided his cases into two classes, those with a good deal of sugar in the urine, but in good general health, who usually did well under dietetic treatment alone; second, cases with considerable sugar in the urine, who had constitutional or special symptoms, who did not get along well under dietetic treatment and perhaps were harmed by it. He approved Dr. Smith's remarks on the danger of too rigid an animal diet, especially if the patients began to emaciate under it.

The Cutaneous Manifestations of Diabetes.—DR. P. ALBERT MORROW read the paper (see p. 508).

Glycosuria Written on the Skin.—DR. G. H. FOX mentioned three cases, one sent him by Dr. Robinson and one by Dr. Sherwell, of glycosuria with an eruption of xanthoma. He laid stress on the similarity of the eruption, a pale yellowish flat nodule on the lower

portion of the back and gluteal region in the three cases, and said it was so characteristic that one might assert when it was present that the diagnosis of glycosuria was written upon the skin.

DR. SHERWELL, of Brooklyn, was glad to hear the remarks of some of the gentlemen to the effect that diet ought not to be too restricted. One was almost criminally negligent who failed to examine the urine of a patient chronically furunculous, or suffering, if a female, from pruritus of the genitals. He preferred a specimen of the evening urine to that of any other period of the day. He spoke of the relation between diabetes and dermatitis herpetiformis of Dühring.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 4, 1896:

	Cases.	Deaths.
Tuberculosis.....	...	...
Typhoid fever.....	14	16
Scarlet fever.....	113	4
Cerebro-spinal meningitis.....	5	26
Measles.....	426	13
Diphtheria.....	193	9
Small-pox.....	0	0

The Microscope in Surgery.—Dr. Senn in a recent work on tumors states that the microscope is not so serviceable in diagnosing tumors as many suppose, and cites as an instance the late Emperor Frederick of Germany. Small pieces of tumor or scrapings of tissue should not be sent to the pathologist simply to see what the microscope will reveal or what the pathologist knows. The object is to obtain a correct diagnosis, and to this end as large a piece of tumor as possible should be sent for examination. It should be accompanied with a history of the case and all other points, such as site, character of growth, etc. In this way the microscope usually decides when the appearances to the naked eye throw doubt on the character of the tumor.

What is Indicated by the Tongue.—A white tongue indicates febrile disturbance; a brown, moist tongue—indigestion; a brown, dry tongue—depression, blood-poisoning, typhoid fever; a red, moist tongue—inflammatory fever; a red, glazed tongue—general fever, loss of digestion; a tremulous, moist, and flabby tongue—feebleness, nervousness; a glazed tongue with blue appearance—tertiary syphilis.—*Medical Age.*

Limited to Skin Practice.—A young physician with an amount of braggadocio altogether out of proportion to his practice was met on the street by an older physician, who asked him how he was coming on. "I have got more than I can attend to," was the boastful reply. "I had to get out of my bed five times last night." "Then why don't you buy some insect powder?"—*Omaha Clinic.*

Cigarettes.—An editorial in the *North West Lancet*, February, 1896, says that to attack the cigarette is to combat the evil in the wrong place. Reform should be begun with the boys who are injured by smoking and not with the form in which tobacco is most attractive to the young. The law should be directed against tobacco in general and not against the cigarette in particular; otherwise the form and not the substance of the evil is the thing attacked.

THE THEORY OF THE THYROID ORIGIN OF GRAVES' DISEASE, WITH ITS BEARING ON THE SURGICAL TREATMENT OF THE DISEASE.¹

By FRANCIS KINNICUTT, M.D.,

PHYSICIAN TO ST. LUKE'S AND THE PRESBYTERIAN HOSPITALS, NEW YORK

THE absence of appreciable pathological changes in one or several portions of the nervous system, in the sympathetic, in the medulla, in the pons, in the spinal cord, and in the higher cerebral centres in many typical cases of Graves' disease, and the necessity of a general involvement of the nervous system to adequately explain the symptom-complex of the disease, have gradually led to a reversion to the hypothesis originally entertained that the disease was primarily one of the thyroid gland, with a very different explanation, however, of its probable pathogenetic influence. The original hypothesis ascribed the nervous symptoms to purely mechanical causes, viz., the pressure of the enlarged gland upon the vagus and sympathetic, and it quickly was seen to be inadequate. Experimental investigations on the functions of the thyroid gland and the knowledge of the vital importance to the economy of its physiological secretion acquired very lately through observations in myxœdema and the closely allied conditions of cachexia strumipriva, cretinism, and fatal rickets, furnish the present basis of the thyroidal theory of Graves' disease. Moebius first suggested that the symptom complex of the disease found its fullest explanation in a general toxæmia of the nervous system, the result of a primary disease of the thyroid gland leading to quantitative and qualitative changes in its secretion, and this view has received the support, with certain modifications, of Wette, Mueller, Joffroy, Béclère, Greenfield, Bramwell, Murray, Maude, and the surgeons Kocher and Rehn, among others.

A review of the evidence at hand in support of this hypothesis is of especial importance, as on its acceptance is largely based the surgical treatment of Graves' disease at present advocated.

It may be summarized as follows:

1. The nature of the pathological changes present in the thyroid gland in many cases of Graves' disease.
2. The antithesis of symptoms present in myxœdema and Graves' disease.
3. The speedy or gradual development of myxœdema subsequent to apparent recovery from Graves' disease.
4. The effects produced by the administration of thyroid extracts in myxœdema, in health, and in Graves' disease.
5. The efficacy of medicinal and surgical measures "which tend to diminish the volume or lessen the functional activity of the thyroid gland" in ameliorating or arresting the symptoms of Graves' disease.

A careful study of the structures of the thyroid gland in Graves' disease is of comparatively recent

date. Published reports of such studies indicate that invariably structural changes varying in degree and kind are present.

Among others Greenfield¹ very lately has given in the Bradshaw lectures the results of his examination in six fatal cases of typical Graves' disease, Grainger Stewart and Gibson² in three, Mueller³ in four, Joffroy and Achard⁴ in five, Vandervelde and Le Bœuf⁵ in four, and Mikulicz⁶ in ten.

The structural changes found by Greenfield, by Stewart and Gibson, and by Mueller were practically similar, and Greenfield's cases alone need be considered.

In all there was an absence of any special vascularity except in the large superficial veins. The changes, although general, were not equally distributed or at an equally advanced stage everywhere, and consisted, in the early stage, in an alteration of the epithelium lining the spaces from a cubical to a columnar type. There was accompanying greatly increased proliferation of tubules and epithelium; little colloid material was present, which seemed to be replaced by a more mucinoid fluid. The newly formed tubules were lined with a single layer of cubical epithelium and in their structure and in the regular arrangement of their epithelium corresponded to the tubules of a secreting-gland. Greenfield further states that as a sequel of these proliferative changes, a catarrhal condition is often found, and in cases of long duration an interstitial overgrowth is developed which gradually invades the glandular structure.

Greenfield summarizes the changes as representing a true hyperplasia and indicating an exaggerated and probably perverted function.

Both Stewart and Mueller also mention the surprisingly small amount of colloid material present in the acini.

From a careful study of the five cases reported by Joffroy and Achard, it would seem that in two the differences in thyroid lesions found from those described by Greenfield, Stewart, and Mueller, is more apparent than real. In a third, a similarity to adenomatous tissue is noted as present in portions of the gland. In a fourth case there was evidence of more or less cystic degeneration; and finally, in the fifth case the gland was replaced by a dense mass of fibrous tissue retaining the form of the gland, with a few heaps of epithelial cells representing the original vesicles. In this case typical myxœdema had supervened on the subsidence of the symptoms of an equally typical Graves' disease.

Of the four cases reported by Vandervelde and Le Bœuf (three personal and one of Raymond's), one was a polycystic goitre, the second probably a fibrocystic goitre; the third case is considered by them to be of doubtful nature, but probably an example of an atypical hyperplasia of the thyroid gland. The lesions found in the fourth case were evidently produced by ligature of the arteries, and consisted of a fatty degeneration of the interstitial connective tissue and the phenomena of necrosis in the epithelial cells of the acini. In the ten cases of Mikulicz, seven are described as diffuse hyperplasias, two as cystic, and one as a hypervascular goitre.

It is evident, therefore, that although anatomically

¹ Read before the Practitioners' Society of New York, April 3d.

an apparent true hyperplasia of the thyroid gland exists in many cases of Graves' disease, lesions of simple goitre alone are found in others exhibiting an exactly similar symptom-complex. Clinically, moreover, it must be recognized that not infrequently cases of both hereditary and endemic goitre of long standing finally develop very completely the symptoms of Graves' disease. Other cases exhibit no other symptoms than increased frequency of pulse, palpitation, and dyspnoea, while in an intermediate class there is an added exophthalmos and general nervous disturbance, yet with an incomplete expression of the symptom-complex of Graves' disease.

Further, it must be admitted that neoplasms of the thyroid gland, of various kinds and degrees which of necessity must be attended with a very considerable loss of secretory tissue, also are associated not infrequently with many, if not all, the symptoms of exophthalmic goitre. Among many others a case of thyroid sarcoma reported by Tillaux⁷ and two personal cases may be cited in illustration. In one of the latter (female, thirty years old), associated with a large fibroadenoma of the gland, there was persistent tachycardia, general nervous disturbance, and slight exophthalmos. In the second case, at present under observation, a boy of twelve years, exophthalmos and tachycardia exist with a recurring (after operation) neoplasm of the thyroid, with a secondary growth in one lung causing marked pressure effects.

An attempt has been made to distinguish these cases as well as those of simple goitre exhibiting the incomplete symptom-complex of exophthalmic goitre as false or surgical goitre, in contradistinction to so-called idiopathic goitre or Graves' disease as classically described with symptoms so numerous, varied, and changeable. With Mueller, Joffroy, and others, I see no justifiable grounds for such a division.

Such cases undoubtedly militate against the thyroidal theory of Graves' disease in so far as hypersecretion alone is regarded as the causative agent, but not if a perverted function with qualitative changes in the secretion is accepted in explanation. Is it not possible that the absence of the symptom-complex of Graves' disease in the majority of cases of simple goitre finds at least a partial explanation in the absence of the neuropathic tendency, inherited or acquired? All clinical evidence indicates the frequency with which Graves' disease appears in families with a strong predisposition to neuroses in general. Moreover, actual neuroses, hysteria, epilepsy, psychoses, frequently have been noted in individuals who later have developed Graves' disease.

The antithesis of clinical phenomena in Graves' disease and myxœdema is so striking and well recognized as to demand but brief consideration. The largest number of cases of Graves' disease occur between the ages of twenty and thirty, during the period of the greatest activity of the generative functions. The interval between forty and forty-five, the period of beginning decline of these functions, furnishes the most numerous instances of myxœdema.

In Graves' disease enlargement of the thyroid gland is present, in myxœdema an atrophy of the gland. In the one case the skin is fine, soft, moist, and warm; in the other coarse, hard, dry with a tendency to desquamate, and cold; in the one perspirations, often profuse in character and easily excited, are conspicuously present; in the other their absence even in the warmest weather is equally noticeable. In Graves' disease the temperature is never subnormal and pyrexia of greater or less degree occurs on slight causes; in myxœdema the reverse holds good. In the former an excitable, mobile pulse, tachycardia, and palpitation prevail; in the latter a sluggish heart action and slow pulse. In Graves' disease irritability and excit-

ability, in myxœdema apathy and dulness of apprehension and perception attract the attention. In the former tremor is one of the cardinal symptoms; in the latter it is absent, except in its rare occurrence in the form of tetany. In Graves' disease the nutrition of the hair, nails, and skin is, as a rule, well maintained; in myxœdema the reverse obtains.

The enumeration of contrasts in the clinical phenomena of the two diseases might be extended almost indefinitely, and the antithesis justly may be regarded as a not unimportant link in the chain of evidence in support of the thyroidal theory.

The speedy or gradual development of myxœdema subsequent to recovery from typical Graves' disease is a strong argument in favor of the thyroidal theory.

In view of the nature of the pathological changes found in the gland in many cases of Graves' disease, viz., an increase in the interstitial tissue in connection with alterations in the parenchyma, and which Greenfield states is a late process, this sequence is explainable on anatomical grounds.

Clinically, a very considerable number of cases have been recorded in which myxœdema has developed at varying intervals after the subsidence of the symptoms of Graves' disease.

Joffroy⁴ reports a single very typical case of this kind; two cases have been published by Bowles;⁸ Gowers,⁹ Ord,¹⁰ Corkhill,¹¹ have seen similar instances, and finally four cases reported by Baldwin¹² in 1895 are of much interest. Briefly their histories are as follows:

CASE I.—Boy; developed classical Graves' disease at about six years of age. He recovered and was typically myxœdematous at eight. Under treatment with thyroid extract all symptoms disappeared.

CASE II.—Girl; in her fourteenth year she developed Graves' disease—tachycardia, pulse 100–116, exophthalmos, enlarged thyroid, etc. All symptoms finally disappeared after an interval of six years, during the whole of which period she was under treatment. During the following year she gradually developed all the symptoms of myxœdema. Recovery followed under treatment with thyroid extract.

CASE III.—Girl, aged fifteen years. Graves' disease appeared six months previous to treatment. Disappearance of symptoms after twenty-one months. Myxœdematous five years later. Recovery under thyroid-extract treatment.

CASE IV.—Female, aged forty-four years. After severe mental shock she developed palpitation, breathlessness, thyroid tumor, exophthalmos, great nervousness, and insomnia. A year later, after final menstruation, all symptoms disappeared and almost immediately were followed by pronounced symptoms of myxœdema. Improvement ensued directly under treatment with thyroid extract and there was rapid recovery.

Several cases have been reported in which the symptoms of Graves' disease and myxœdema are believed to have been associated. Of the two cases published by Sollier,⁵ one presented with evidently true Graves' disease a coincident œdema of an intermittent nature. Further evidence is needed before ascribing the symptom to a myxœdematous origin. In the second case a true example of myxœdema is described: the evidence of Graves' disease after admission of the patient to hospital consisted of a slight degree of exophthalmos, especially on one side, in a pulse of 110–120, running up to 160 on slight emotion, and in diminished electrical resistance.

One of these cases, according to Murray, was treated later with thyroid extract without improvement in the myxœdematous symptoms, which is presumptive evidence against the origin ascribed to them by Sollier. (I have been unable to distinguish which of the two cases was so treated.)

Kovalevski¹⁴ reports a case in which myxœdematous

swelling, apathy, anæmia, and slow speech developed in the course of Graves' disease. The symptoms of myxœdema disappeared under treatment with hot baths, galvanism, arsenic, and quinine. The patient was still living at the time of the report and still suffering from the symptoms of Graves' disease.

Von Jaksch's case¹⁵ simply presented swelling of the lower extremities, which he believed to be of a myxœdematous nature.

Chvostek¹⁶ found the skin of a patient with Graves' disease "probably œdematous but leaving no pitting."

Osler¹⁷ reports a case with slight myxœdematous symptoms—slight swelling of the face and pads of the fingers—associated with enlargement of the thyroid. Exophthalmos was not present; pulse 84.

These are the only cases I have been able to find in which the symptoms of the two diseases have been believed to be associated. Their very limited number renders any conclusions of little value.

It should be borne in mind that fugitive and unsymmetrical swellings of various parts of the body, especially of the cheeks and eyelids and clearly of vasomotor origin, are not uncommon in Graves' disease. Such cases have been described by Parinaud,¹⁸ Hector Mackenzie,¹⁹ Gowers,⁹ Maud,²⁰ and Vigoroux.²¹ One case of swelling of the eyelids has come under my personal observation.

The effects produced by the administration of thyroid extract in health and in myxœdema are now well recognized. The susceptibility to its action in individuals in health undoubtedly varies somewhat, but doses rather larger than those found useful in myxœdema frequently increase the pulse rate from forty to fifty beats. The accelerated heart action is accompanied with palpitation, flushing, a feeling of fulness in the head, slight tremors, with profuse perspirations.

An especial susceptibility of patients suffering from myxœdema to the action of thyroid extract certainly exists. Large doses almost invariably produce pulse acceleration and palpitation, the temperature rises above normal, the skin becomes flushed and moist. If the dosage is pushed, there follow insomnia, restlessness, polyuria, diarrhoea, often fine tremor. Bécclère²² observed in a myxœdematous woman who took by mistake at the beginning of treatment ninety-two grams in eleven days, tachycardia, irregularity of pulse, elevation of temperature, insomnia, polyuria, glycosuria, albuminuria, incomplete paraplegia with heat sensations, perspirations, transient tremor of the arms, and slight exophthalmos.

It is needless to call attention to the similarity of these symptoms to those presented by the patient suffering from Graves' disease; they embrace almost the complete symptom-complex of the disease. They are such as would be anticipated if the symptoms of Graves' disease are dependent upon an exaggerated function of the thyroid gland.

The effects of the thyroid extract in Graves' disease are too varied for any definite conclusions. It is true that its administration in many cases is unattended with appreciable aggravation of the symptoms; it is equally true that in a similar number of cases its use causes a distinct increase in the characteristic disturbances of the disease. Several reported observations of improvement in the symptoms of exophthalmic goitre during the use of thyroid extract justly admit of doubt as to their correctness. In the most interesting case of this kind, reported by Owen,²³ it was discovered by him later that an extract of the *thymus* gland had been given to the patient by mistake.

The efficacy of medicinal and surgical measures which tend to diminish the volume or lessen the functional activity of the thyroid gland, in ameliorating or arresting the symptoms of Graves' disease, is at present recognized.

The good results obtained from the use of belladonna are probably due to its power of inhibiting to a greater or less degree the functions of secreting-glands. Murray has found that the inunction of the red iodide of mercury ointment over the enlarged thyroid reduces its size and coincidentally causes a distinct diminution in the symptoms of the disease.

Partial extirpation of the thyroid gland by one or another of several surgical methods, and necessarily attended with a marked diminution in the volume of its secretory structures, has been followed by a subsidence of many, if not all, of the symptoms of Graves' disease and in a large number of cases by complete recovery.

I have been able to collect one hundred and eighty-seven cases surgically treated. In the tabulated list, the results have been entered under the heads of "Death," "Cured," "Improved," "Unimproved," and "Unknown."

The precise statement of reporters or operators in regard to improvement or recovery has been accepted. Where this is not made no case has been included among the recoveries, unless all symptoms with the exception of exophthalmos have disappeared.

A summary of the table shows that 13 have died as the more or less immediate result of the operation, thus giving a mortality of about seven per cent.; 60 are reported as having recovered, 47 improved, 11 unimproved; in 25 the result is unknown. In addition, 31 cases operated on by Kocher have resulted in various degrees of improvement, amounting in some cases to complete recovery. These would therefore increase the totals of cured and improved, but I have not been able to determine the number belonging to each.

In addition to the deaths included above, two patients died from causes not attributable to operation, in each case about two months later (influenza, sarcoma of lungs).

Four of the cases reported as improved had relapse of all symptoms after periods of two months, one year, two years, and seven years, respectively.

It is interesting to note that, as a rule, the longer the period of observation after operation the better appear the results. The psycho-neurotic symptoms would seem to be among the first to subside; a marked diminution in the pulse rate occurs more gradually. The exophthalmos apparently may persist long after all other symptoms have disappeared, in fact after practical recovery has been obtained. In two patients who have come under my observation such has been the case. In Case 10 of the tabulated cases, the patient was under my observation in hospital both before and after operation, and it is of interest to mention that there was a marked diminution in the degree of exophthalmos in the twenty-four hours succeeding the partial removal of the gland; there was no further improvement during the subsequent month. In the same interval the marked psychical disturbances had almost wholly disappeared, the tremor completely, and the pulse rate had fallen from 140 to below 100.

It is thus seen that the effects of medicinal and surgical measures in relieving the symptoms of Graves' disease apparently through reducing the volume of the gland strongly support the thyroïdal theory. Instances—and they are not inconsiderable in number—in which, by removal of pathological conditions elsewhere in the body (polypi and other disease products in the nasal passages—Spicer,²⁴ Stoker,²⁵ Winckler,²⁶ Fraenkel,²⁷ Semon;²⁸ diseased kidney—Barella²⁹), the symptoms of exophthalmic goitre have subsided or disappeared, need not necessarily be accepted in disproof of this theory.

As Putnam says, "morbid processes may be perpetuated by influences which were not their real cause and cease when these influences are withdrawn."

Moreover, the spontaneous and rapid disappearance of even the symptom-complex of Graves' disease in occasional cases, and complete recovery in others after several years of illness, indicate that *extensive* structural changes in the thyroid are not always present; and may it not be that in such cases peripheral irritations elsewhere in the body are sufficient to maintain a functional hyperactivity of the gland which ceases on the removal of the irritation?

The apparent absence of enlargement of the thyroid gland in exceptional cases otherwise presenting the symptom complex of the disease has been cited in disproof of the thyroid hypothesis. Mueller³⁰ reports one such case, in which, however, structural changes were found after death, and it is not improbable that similar conditions would be found in others in which during life appreciable enlargement was absent.

Finally, in further evidence of the thyroidal origin of the disease may be mentioned the well-known aggravation and diminution in nearly all the symptoms, simultaneously with an increase and decrease in the volume of the gland, which occurs so frequently in the clinical history of Graves' disease.

The main points of evidence in favor of the thyroidal theory have been presented, and incidentally observations which would seem to militate against its correctness have been considered.

In conclusion it would seem that a preponderance of both pathological and clinical evidence is in favor of the view that the symptom-complex of Graves' disease finds its most satisfactory explanation in a general toxæmia of the nervous system, the result of quantitative or qualitative changes, or both, in the secretion of the thyroid gland; that for the complete expression of the symptom-complex of the disease the existence of a neurotic predisposition is probably necessary; that the *ultimate* cause of the disease of the thyroid gland is still a matter of speculation.

The growing disposition to treat Graves' disease by surgical measures tends to the inquiry whether it is the best and most efficient treatment. In an attempt to answer this question the dangers of thyroidectomy or of extirpation by other surgical procedures must be carefully considered, as well as the degree of benefit which may be expected from operation.

In simple goitre the symptoms for which relief is sought are similar in character to those of Graves' disease, although of less complexity and slighter in degree, and the record of Kocher alone indicates the slight mortality attending extirpation of the gland.

Notwithstanding his brilliant results, Kocher,³¹ at the last meeting of the Congress of German Surgeons, expresses his hope that another treatment than a surgical one for these cases may be found. He even states that the results obtained by himself and his assistants by dietetic treatment and by the use of the phosphates has been sufficiently encouraging to emphasize this hope.

In well-developed Graves' disease, not only is the mortality from operation much larger, but also the occurrence of alarming symptoms during and immediately after operation is not infrequent.

The occurrence of sudden death, which occasionally takes place during operation, has not as yet received a satisfactory explanation. Putnam suggested the rapid absorption of thyroid secretion from the cut surface of the wound, but now considers this explanation improbable.

The alarming symptoms consist in extreme prostration, excessive tachycardia, and dyspnœa, and to these may be added the occasional dangerous accumulation of mucus in the larynx and trachea.

Wette considers injury of the recurrent laryngeal nerve to be the probable cause of some at least of these disturbances. As Putnam has pointed out, the

seriousness of the tachycardia and dyspnœa may be more apparent than real, being no more than exaggerations of similar paroxysms often observed in cases not operated upon. In a case of classical Graves' disease at present under observation, frequent attacks of extreme dyspnœa and tachycardia (pulse 200) and attended with great prostration, occurred during a period of several years. The paroxysms would subside as suddenly as they appeared, leaving the patient in comparative comfort. All the symptoms of the disease in this case have been subsiding gradually during the past twelve months, without operation and after an interval of seven years from the beginning of the illness.

Nevertheless, an irritability and probable weakness of the heart, even in the absence of structural changes, in Graves' disease must be fully recognized in deciding for operation.

The paralysis of the laryngeal muscles which frequently occurs after thyroidectomy fortunately disappears, as a rule; often, however, only after an interval of months.

Of the two operations chiefly advocated, ligation of the thyroid arteries and partial thyroidectomy, the former is earnestly advised by Kocher and Mikulicz in preference to resection, on account of its greater safety. Ligation of three arteries rather than of four is practised by Kocher. The observation has been made that every surgical measure which diminishes the size of the gland leads to its gradual further shrinkage or atrophy. The evidence in regard to the benefit to be expected from any operation which tends to diminish the size of the thyroid gland is clearly given in the appended tables.

It would seem from their study that more rapid and greater benefit in a larger number of cases occurs through operative than under medicinal treatment. On the other hand the high mortality rate up to the present time of the surgical treatment of Graves' disease must exclude it as a routine measure. It should be employed only, in my judgment, when all therapeutic measures have been fairly tried and have failed. The class of cases in which surgical treatment would seem especially advisable or indicated are those of not too long duration and with symptoms sufficiently severe to produce disability.

THE EVOLUTION OF THE SURGICAL TREATMENT OF THE BROAD-LIGAMENT PEDICLE.

By LAWSON TAIT, F.R.C.S.,

BIRMINGHAM, ENG.

A VOLUME which I published in 1891 was devoted mainly to the establishment of severe operative procedures for the relief of diseases of the pelvis and abdomen, especially in women. It dealt chiefly with the leading features of these proceedings in the direction of reducing their primary mortality and establishing them on the basis of giving a reasonable return for the risks run. This result has now been fully accomplished, and if I had confined myself strictly to these themes in my first volume my second would have been ready long ago; but the making of the first effort toward the latter has been put off till to-day, for in the second division of my task I have found so much to reconsider that over and over again I have been compelled to delay, until at last the task has seemed to me wellnigh hopeless, and I have felt that I should have to leave it to other hands to accomplish. In the intervening six years the field of surgical literature has been flooded with contributions on abdominal surgery—some good, a few very good, very many indifferent, and the great bulk hardly worth notice. I have waited to see if any one would take up what seems to me the logical method of advance, but I have found none to do so; and the effort which I now begin to-day to produce my second volume, and to indicate the lines on which I have improved and still hope to improve the secondary results of our operations, may turn out to be a failure as great as any which I have just deprecated. If, however, it have anything like the success which my first volume has met with I shall be pleased indeed, and in my own opinion the second will greatly transcend the first, alike in interest and importance.

As the whole history of abdominal surgery, in the slow and tardy evolution of its first stages, turned on the treatment of the broad-ligament pedicle, so my first efforts in the secondary evolution necessarily start at the same point; and it is, to say the least, disappointing to me to see how little the importance of this subject has taken hold of the men who have written most fluently on abdominal surgery and who have brought out the most popular text-books.

Mr. Greig Smith's book, for instance, will, to its ordinary reader, seem sufficiently imbued with my own teaching, yet he says concerning the treatment of the pedicle: "It has always seemed to me that this *question vexata* of ovariectomy has been unduly magnified in its importance. To a surgeon accustomed to deal with amputated limbs the pedicle is, comparatively, a small matter." If this is the view generally of surgeons accustomed to deal with amputated limbs, I hope fervently that no one in whom I have any personal interest will ever fall into their hands for the treatment of an ovarian tumor. Coming from the pen of a man like Greig Smith, it can only mean that, while he has written freely and with confidence, he has not seen a sufficient number of ovariectomies to know how different these pedicles can be, and his comparison of them with the symmetrical and constant incidents of amputated limbs is the most perfect nonsense. Similarly, the experience of one or two cases in which chronically over-distended bladders may be tapped for ovarian cysts, or even attempts made to remove them by abdominal sections, will some day cause him to repent bitterly of the following sentences: "I think that the advantages of catheterism before operation are somewhat exaggerated. I am convinced that it is unnecessary, and I have never done it."

From these illustrations I am persuaded that the

creation of abdominal surgery into a special branch of surgery was a wise movement, on the same ground that the development of ophthalmic surgery has upset the advice we used to find in a few chapters on diseases of the eye, oddly enough placed at the end of text-books on practice of medicine, that in all classes of squint the muscles supposed to be at fault were to be freely divided.

It may be useful to continue my criticism of Mr. Greig Smith's text-book on one other point, and that is his expression of opinion that "the operation of Houston of Glasgow (1701) was almost certainly not a complete ovariectomy." But apart from the very conclusive fact that the patient lived afterward in perfect health for thirteen years—a similar occurrence is not known in my own experience of incomplete ovariectomies—Mr. Greig Smith only lays himself open again to a charge of defective experience. I could not understand why Houston should describe his proceedings with such photographic fidelity of detail and say nothing about his treatment of the pedicle, and I assumed that he must have divided and tied it and forgotten to mention the fact. I did not attach sufficient importance to the fact that Houston had met with one of those singular eccentricities of ovarian growth with which my own long list is interspersed in goodly number, and it was not till I began to dig them out and carefully investigate their details that I saw the probability of Houston's description being perfect, even in the absence of allusion to the pedicle and its treatment. The clew is in his words: "I took a strong fir splinter, such as the poor in that country use to burn instead of candles; I wrapped about the end of this splinter some loose lint and thrust it into the wound, and by turning and turning and winding it I drew out above two yards in length of a substance thicker than any jelly, or rather like glue fresh made and hung out to dry; its breadth was above ten inches; this was followed by several large pieces of membrane which seemed to be parts of the distended ovary. I then squeezed out all I could and stitched up the wound," etc.

When I got a group of my own cases together it was easy to see that Houston's belonged among them, and that they form a class by themselves and have peculiarities of their own, not the least curious of which is that they probably present the examples of ovarian tumors undergoing spontaneous cure—examples which beyond all doubt occur, but which are so rare that they may be certainly disregarded in any discussion of treatment.

These cases have all the same character, and no description can be better than that of Houston's own experience. The cyst walls are always thin and, so far as my memory and my notes serve me, the tumors are sessile. In these well-marked and entirely similar cases the cyst walls had given way and the gluey contents were diffused throughout the abdomen. The cyst walls, or rather their remains, were isolated by washing out and were then found to be mere shreds, patches, and strings of membrane with attached masses of cystic proliferation, by which only their inner surfaces could be recognized. These shreds and patches were quite rotten and came away from their very vague attachments in the pelvis on slight touch, no ligatures being necessary. In each case drainage tubes were left in at the close of the operation, and large quantities of the gluey material more or less in solution were discharged for some days.

My belief is that in none of these three cases was the operation really necessary. Had I left them alone the gluey material would have been slowly absorbed and the shreds and patches would have contracted and disappeared, unless they had developed malignant tendencies, and there is a suspicion that this did happen afterward in one of my cases. This is a

secondary termination from the risk of which no ovariectomy is free.

These three cases are, therefore, on precisely the same level with Houston's, only I did a little more scientifically and with better tools what he did as effectively with a stick. What is the explanation of such cases? That question I can answer only by speculation. True pedicle they have not, and it seems to me as if at a certain point the cyst contents have a digestive power over the cyst walls and that in time the peritoneal surfaces digest the cyst contents. It may be that when we come to the base of the tumor and pull away the rotten remains we complete the process by a rough enucleation, but I really cannot say. I saw the base of attachment of these three tumors, and Houston did not see his; therefore he said nothing about it. But I saw mine with the eyes of the blind, and only at my next experience will my eyes be open wide enough to get a true record of the state of matters.

Meantime I have said of Houston that the earliest known treatment of the ovarian pedicle was probably by enucleation.

Houston's operation makes a most interesting and picturesque addition to the early history of abdominal surgery, but it has no value at all, although it was published in the stately transactions of the Royal Society of London, which were read, then as now, with avidity all over the world. He found no imitators.

The first really deliberate and systematic attempt to do serious operations for abdominal disease was that of Ephraim McDowell. It was of course received with the only argument with which it could be met—that constant refuge of human imbecility—that McDowell was a liar, and the historical fact is on record that an editor of a medical journal who spread the libel had to "eat dirt" and "beg pardon of God and Dr. McDowell." Nowadays there seems to be no such fear of the Deity among medical editors, but some day one of them will have to make similar apologies.

McDowell's method of dealing with the pedicle was that which he learned from John Bell in Edinburgh, and which was applied to all arteries and to everything containing an artery down to my own time—the long ligature. In a stump the arteries were tied with a hempen ligature; one end was cut short and the other left long, the series to decorate the suppurating stump for many days—the amusement of the house surgeon and the terror of the patient being their removal by tugging as soon as they would come. Often they never came. Why it did not strike some one to try how they would answer if both ends were cut short I cannot imagine. But the difficulty set Simpson's ingenious mind to work with his visionary acupressure, and he unconsciously cleared out the long ligature. How the short ligature came into use in general surgery I do not know. It appeared early in the history of ovariectomy, but most unfortunately only for a short time.

In 1822 Nathan Smith, of New Haven, Conn., did his first case with the short ligature, dropping the pedicle in, and he followed this by a series of cases so successful that it must ever be the amazement of historians of surgery that his example was not at once followed. His lesson was far more valuable than McDowell's and his action more philosophical, for he argued out the necessity for the short ligature and he used animal ligatures (pieces of kid glove) in the belief that they would be absorbed—a conclusion most abundantly proved to be correct. His lesson was neglected, I suppose on the ground that he also was set down as a liar; at any rate, he must have been so regarded in this country, for his statements were widely published here, yet the long ligature held sway till the advent of Baker Brown in 1851. He in turn introduced the treatment of the pedicle by the cautery, obtaining his idea doubtless from veterinary surgery.

A most unfortunate incident occurred soon after this in the invention and introduction of the clamp treatment of the broad-ligament pedicle—an incident, according to his own authority, to be laid at the door of Mr. Jonathan Hutchinson.

The short ligature was reintroduced and reinstalled almost simultaneously in 1878 by Bantock and myself, and has since remained the only method of dealing with the broad-ligament pedicle, except by the cautery and clamp, which were used by Keith to the last. Up to that time we were all astray except Keith, for we used Hutchinson's clamp, with mortalities running between the dreadful limits of twenty-five per cent. and fifty per cent. Keith alone, adhering to Baker Brown's method, brought down his mortality and swept the world with his brilliant success. Very soon, however, Keith's record was beaten by the ligature, and then it became manifest that the main principle to be followed for success was that of the intraperitoneal replacement of the divided and secured pedicle, and that there was little to choose, so far as promising results were concerned, between the cautery and the short silk ligature.

As I watched Keith operate in 1880-81, I became convinced that the ideal method of pedicle treatment was by cautery, but for the great length of time and the large amount of physical exertion involved. Keith and I, in a half-jesting fashion, agreed to stick each to his own method and after a long series of cases to compare results. But Keith ceased to publish under conditions which made comparison possible, and the contrast has never been made.

Still, I do not think that any other conclusions than these I have indicated could ever have been derived.

I have, however, been haunted ever since by the clear thin line of parchment to which Keith reduced his pedicles, and I have often looked at my own, regretting the dead lump of wet and decomposable tissue I had to leave, girt by a dead and decomposable ligature. But still it is certain that the great bulk of these difficulties were successfully encountered by that wonderful power which living tissue has for removing dead matter, a power for which so many strange theories have been advanced of late years without leading us much beyond the facts.

I have not yet seen a case in which post-mortem examination made it evident that death was due to the ligature, though I have seen several, some among my own cases I regret to say, in which faulty application of the ligature has been the cause of death. If the ligature is so applied that it controls hemorrhage completely, the ligature does not contribute in any way, so far as I know, directly or indirectly to death.

But it has a most unfortunate way of contributing to secondary failure, to incomplete cure, and to persistent and vexatious interference with convalescence.

The first of the instances of this kind to be mentioned as being never fatal, but as being the more common and more alarming of the two, is the occurrence of broad-ligament hamatocele. Speaking to Keith about this, his answers impressed me with the belief that the accident did not occur in his practice, and he was far too shrewd and anxious an observer to miss it if it had occurred frequently. The users of the clamp certainly did not place its occurrence on record; but, with a mortality of twenty-five per cent. raging round them, it is not likely that they would observe it if it did occur, and when it occurred I think death must have been inevitable. I cannot imagine any more certainly fatal combination than a broad-ligament hamatocele and septic stump. But still the question stares us in the face, does the ligature cause or facilitate the occurrence of broad-ligament effusion? I confess I strongly suspect that it does, and this is one of the reasons for my present paper.

The second incident which tells against the ligature is the occurrence of a number of cases, three or four per cent., in which the garotted stump and ligature get the better apparently of the living tissue around them, prevent the tissues absorbing them, cause suppuration, and form sinuses which do not heal, but go on discharging till the knot of thread is got rid of, months—it may be years—after the original operation. Sometimes the ligatures burrow into sinuses of the broad ligament and are discharged into the rectum and bladder. Quite a group of these latter cases has now occurred in which I have removed knots of thread from the bladder contained within a thick deposit of phosphates, some of the ligatures having been originally placed by myself, some by others. How these ligatures travel in this way is a matter of easy explanation and that is I think as follows: Suppose the ligature to be placed on the right pedicle; it will go (as a matter of fact three of my own have so travelled) into the bladder; while if it be a left broad-ligament pedicle to which the ligature has been applied it will more likely get into the rectum. In fact, as I have often had occasion to observe in operating for pelvic abscesses, the bladder seems the road out of the right broad ligament and unquestionably the rectum is the point of election for the natural evacuation of the left parametric cavity.

The method of inclusion of the ligature is curious and interesting, for it seems difficult to imagine at first thought that a ligature tied inside the peritoneum would, as a matter of course under certain conditions, work its way through that membrane and into an extraperitoneal district. It happens thus. The ligature is tethered to the floor of the pelvis by the vessels and nerves it embraces. The peritoneum is raised up around it and finally over it by the increasing effusion of blood, until a tube of inverted peritoneum is made with the ligature at the base of it. The mouth of this inverted tube is closed by adhesion at its intraperitoneal end and opened at the ligature end by the subsequent suppuration, and the loosened ligature drops into the increasing and purulent cavity of the broad ligament. Its subsequent journey is a matter of notoriety and of long and protracted suffering for the patient. I could, unfortunately, point to a number of my patients who have been for months and even years undergoing this torture from what I call "a dead ligature." I have made various attempts to relieve them—some I am glad to say successfully, and others I regret to say with failure. But they will get well in time and none, so far as I know, has died in the process.

For these two reasons I want to get away from the ligature if I can, and after years of experimenting and thought I think I have at last succeeded. But the difficulties have been so great that I have not yet ventured to apply my plan to a living subject. Fortunately, however, for my consistency, dead animal tissue is helping me and experiments on animals are unnecessary for this purpose at least. My constant feeling has been that in the cautery we should find the solution of the difficulty; and it shows how careful we ought to be in all our experiments in surgery that it was not till after at least two years' consideration of the subject that it dawned on me that we did not understand how the cautery really works. I do not think that either Baker Brown or Keith understood how they arrived at their certain and magnificent results. I am sure the bystanders did not. Every one of whom I have asked questions has answered: "Oh, yes; sear the stump! barbarous practice, going back to the days before Ambrose Paré!" But Keith did not sear the stump. It is true he burned a piece of it off after securing it with Baker Brown's clamp, and if searing had been the means of his success he would have stopped there. But he went on for about twenty minutes or half an hour rub-

bing the clamp with his cautery and clearing it with towel or sponge, until the onlookers got weary of the proceeding and thought Keith was finical. What he had done was really this, and I found it out only after much experimenting: he had seized a transverse strip of the pedicle between the iron blades of his clamp, screwed the blades up tight, and then heated them up to the cooking-point (that is, practically, between 180° and 190° F.) and carefully maintained that temperature till the enclosed strip of pedicle was cooked dry into a strip like parchment. Now Keith either did not understand what he was doing, but acted merely by rule of thumb, or else he kept his real reason for using the cautery a profound secret. Had he seared the tissue, the probability is that either hemorrhage would have occurred soon after the patient recovered from shock, or that the burned mass would have caused pelvic suppuration—it could not have been absorbed.

Having satisfied myself of the validity of this exclusion, I set to work to contrive a better method of arriving at the same results, and after many failures I have found it in the method of cooking by electricity. Knowing the resistance of a certain piece of platinum wire, I embed it in a box of silver and isolate it by means of plaster-of-Paris, kaolin, or pipe clay. Two such boxes are placed face to face and connected by the necessary binding-screws. The boxes are placed opposite each other on a pedicle and are screwed together. An electric current, of known strength and under the control of a rheostat or a Kelvin's balance, is now turned on to heat the boxes; or better still, the boxes are heated first and then applied to the pedicle, as this method saves time. The boxes are enclosed in ivory or other bad conductors of heat, to save alike the heat and the tissues for which the heat is not wanted, though this precaution may be dispensed with. The apparatus I use will in a period of from six to eight minutes so cook an ordinary pedicle that hemorrhage will be impossible and suppuration unlikely in the extremest degree. The contrivances are rough, but they are in process of amendment, and the same principle is being applied to instruments for the arrest of visceral oozing, for parietal and omental hemorrhage and for the simplification of the operation of total removal of the uterus. For operating on hemorrhoids I do not advocate my proposals as likely to reduce the primary mortality; I believe that has been done so far as may humanly be possible. But I am quite sure that they or others on similar lines will go far to secure secondary results more satisfactory and more encouraging alike to our patients, to ourselves, and to the art of surgery. I have no doubt the new electric hæmostat will find many fields of usefulness in general surgery.

Statistics of Lactation.—Dr. Wiedon (*Centralblatt für Gynäkologie*) has collected interesting statistics at the Freiburg Maternity. Out of five hundred and twenty-five in childbed only one-half could suckle thoroughly during the first two weeks. Ninety-nine secreted no milk; forty-nine had imperfect nipples; forty-six fissured nipples; and forty-four insufficient secretion of milk. Only thirty-three suckled without unfavorable complications. Wiedon groups breasts into three classes. According to the percentage of his series good breasts give fifty-six per cent.; medium, twenty-one per cent.; bad, eleven per cent. The development of the nipple bore a direct relation to the value of the breast as a secretory organ.

Individual Communion Cups have been adopted by a Presbyterian Church in Jersey City, and were used for the first time on Easter Sunday.

TWO BLOKES' EARS SEEN IN THE VATICAN BELVEDERE DURING AN ITALIAN TOUR.

BY SAMUEL SEXTON, M.D.,

NEW YORK.

THE slang term "bloke" is of obscure origin. It is used as a term of disrespect, derision, or ridicule, and is applicable, therefore, to the ancient Greek or Roman boxer, who was a much more ferocious person when wearing upon the hand a cestus made of leather thongs formidably armored with iron or lead than is the modern pugilist. Brutal contests with this weapon are no longer tolerated unless among certain savage Asiatics. It is to the selection by Canova of the Greek bloke as a model for his famous statues, "The

guided young man from the East who had been deluded into going all the way to Paris to undergo a "hydrophobia" cure. The *Nubia's* crew were mostly Mohammedans from several different localities of India, attired in the highly colored costumes of the place from whence they came. They were very agile and constantly skipped about the decks, presenting a fantastic picture. But few of them understood English. They were temperate, reliable, could endure the extreme heat of India, and were more easily disciplined than European sailors. But few persons realize that this class of her Britannic Majesty's subjects are so numerous, and probably outnumber the Moslem population of any other nation.

We had gone aboard the *Nubia* at Gravesend some hours before the arrival of the tender which brought down the passengers from London. Their embarkation

Boxers," that we are indebted for the perpetuation in marble of the peculiarly deformed ears of the ancient pugilist. Before describing these works of art I may state that it was my intention last autumn to attend the International Otological Congress which was to meet in Florence in September, but unforeseen circumstances prevented. Meeting with an English friend in London, however, it was arranged between us to make a tour of Italy together. We selected a very pleasant route to the Mediterranean, namely, the Peninsular and Oriental steamship line. We took passage on the *Nubia* of this line, sailing from London for Naples on September 27th. She is one of the company's smaller steamers. The fare and other accommodations were good, and she offered the advantage for those who like the sea of going at a rate of only twelve or fourteen knots an hour. Most of the passengers were military or civil officers, and in some instances their wives and relations, bound for Gibraltar, Tangiers, British India, etc. There were also a number of tourists, a tiger-hunting lord, and a mis-

with their belongings of various kinds was an interesting scene, and the final parting of relations and friends, who were separating for years, or perhaps forever in some instances, was touching in the extreme. We were glad when the despondent crowd left the ship, and the bracing air, when the vessel swung around into the channel, soon had a cheering effect on the saddest passenger. On steaming out of the mouth of the Thames it was yet daylight, and we soon afterward found the Channel fleet at anchor in the Downs. The massive iron vessels loomed grandly up in the early twilight as they lay in grim repose upon the dark steely water. The third day out found the *Nubia* in the much-maligned waters of the Bay of Biscay, which were now as quiet as any duckpond. On the fifth day we came to anchor in the Straits under the shadow of Gibraltar, or the "Rock," or "Gib," as the place is familiarly called. A brief visit to the Rock afforded an opportunity to secure some Moorish coin and a silver dollar bearing the bust of Spain's baby king, and on coming aboard again the anchor was taken up

and the *Nubia* put her prow into the dark blue waters of the Mediterranean. The blueness of the water was very observable, and for hours when not gazing down upon the sea the eye was drawn to the snow-capped Sierra Nevada range of mountains, whose bold rocky coast line lay before us. Every now and then as we sailed along, there came into view the old watch towers which centuries ago the Moors had placed upon prominent rocky promontories, during their occupancy of Spain. Whatever habitations there were could not be detected by the eye, and one was left to indulge freely in picturing the country as it was when under Moorish sway. On the eighth day of our voyage the rugged easterly coast of Sardinia gradually came into view and, sailing around it, we came to anchor in the beautiful Bay of Naples the following morning.

The Italian and Spanish coasts have a beauty of their own which only the pen of an Irving could bring into a picture as complete as his "Alhambra." The mar-

wonderful, and among the objects of interest are the works of art in the Vatican palace. It was here that we found the "The Boxers" in the Belvedere, which are of special interest to the otologist.

I had heard that some of the works of ancient sculptors displayed those deformities of the ear so common among boxers both ancient and modern, and known to alienists as *othæmatoma*, and have alluded to the fact in my work on the ear.¹ We soon found ourselves viewing the studies in marble known as "The Two Boxers" of Canova. The figures represented the ancient Greek contestants Creugas (Fig. 1) and Damoxenus (Fig. 2). My companion, who is up in anatomy, exclaimed, "Look at the blokes' ears!" and sure enough here were the figures I had long wished to see. Fortunately I secured good photographs of them, which are here exhibited.

From the life of Canova, by Henry Morris,² I abstract the following legend, from which the artist is supposed to have drawn his inspiration:—The ancient

FIG. 1 a.

FIG. 2 a.

vellously beautiful sky always glowed at sunset with warm-colored tints, unless arrayed in green, as it sometimes was. What wonder that a people bred in such a climate, under such skies, are naturally both musical and artistic? No other countries but Spain and Italy ever produced a Cervantes or a Boccaccio. The early October weather in southern Italy was delightful—the temperature in Naples was about 70° F. day and night. During our brief stay in Naples we of course visited Vesuvius and the ruins of Pompeii; at the latter place excavations have brought to light the armamentaria of the pagan surgeons as they hastily left them eighteen hundred years ago. One may find instruments similar to those of Pompeii in many places where Roman legions camped and left evidences of the ancient cutlers' art. I once examined at Homburg a collection similar to that in the museum in Naples; it had been discovered in the Roman camp situated upon the Taunus range near Homburg.

I was surprised to find so little good fruit in Italy; the only obtainable kind was the fig, though a few excellent lacrima-Christi grapes remained on the vines of Vesuvius. The apples and other fruits served were hard and without flavor, but were eaten by the natives.

The attractions of Rome are of course known to be

Greeks, though highly refined in some aspects of their character, delighted in fatal and revolting athletic contests in which the combat was not complete without avowal of defeat by one of the antagonists, which their obstinate courage usually delayed until all strength was gone—sometimes even life itself. The combat here depicted between Creugas and Damoxenus, as recorded by Pausanias, was both cruel and revolting. These Argives and pugilists were contending at the Nemean games, their hands strengthened by leather thongs, when, victory remaining long undecided, it was agreed that each combatant should alternately give a blow to his antagonist and receive one in return. Creugas, having to give the first blow, struck his adversary on the head, but without any decisive result. Damoxenus, before returning the blow, required that his adversary should place his left hand on his head, which being done, he drove his armed hand into the exposed side of Creugas and, penetrating to his entrails, tore them reeking from his body. The unfortunate Creugas fell and expired on the spot. His pitying countrymen placed the olive crown upon the head of

¹ "The Ear and Its Diseases," Wm. Wood & Co.

² "Works of Canova in Sculpture and Modelling," Bohn, London.

the dying Creugas and, struck with horror at the deed, condemned the ferocious conqueror to perpetual exile. The combatants are represented at the moment when Creugas, having first struck his adversary, stands with unarmored hand raised to his head. The rigidity of muscles from his posture exposes the savage design of Damoxenus.

The attitude of these contestants, as shown in Canova's statues, may be artistic and indeed strictly after Grecian models, but it does not altogether represent the posture assumed by modern pugilists. But since the right hand was strengthened by the cestus, the result of the combat was very different from those of to-day. A blow upon the ear might prove fatal, and, moreover, it would seem that the hand armed with the cestus could be made to penetrate the abdominal walls.

The enlarged pictures of the ears, Fig. 1 *a* and Fig. 2 *a*, illustrate the deformities due to traumatic injury of the auricles in pugilists, which are frequently met with in this class of subjects at the present time.

FIG. 1.

FIG. 2.

The auricles, as here shown, have lost their graceful outlines by reason of previous contusions.

Sometimes the deformity is much greater than exhibited above, as may be seen in Fig. 3, in which the parts have been laid open with the surgeon's knife. Fig. 4 represents an auricle in which fluid is yet present in the tumor, the ear having received a blow some days before the photograph was taken.¹

Infant Feeding.—Dr. Cheney (*Occident Medical Times*) believes that mothers usually feed their babies too often. At first the interval should be about one and a half hours; at six weeks give food every two hours; three months, every at three hours; and at six months, give every four hours, and keep that interval from then on. As to the manner of feeding, he says we all have seen failures in infant feeding, not due to quality, quantity, or irregularity, but due to bolting the food. We cannot do so ourselves without suffering thereby. The baby is usually given the bottle and literally "swills" its contents down, a whole bottleful, which is the source usually of the indigestion. The nurse or mother should handle the bottle and allow the baby fifteen minutes to drink what may be in it.

UPON THE IMPORTANCE OF DIGITAL EXAMINATION IN THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE THROAT AND NOSE.¹

BY SAMUEL KOHN, M.D.,

NEW YORK.

Too much stress cannot be laid upon the importance of diagnosis in the practice of medicine. Whatever progress our science has made, whatever triumphs it has achieved, have been based upon the careful study of disease processes and their recognition. Microscopy and bacteriology, in whose development the brightest intellects of the scientific world are enlisted to the end that the apparently inscrutable secrets of organic life may be made as clear as day, are the results of this striving to know intimately the pathological processes to which flesh is heir. Clinically palpation and digital examination have ever been considered of the highest importance in physical diagnosis; although in this branch of medicine inspection ranks first, inasmuch as it conveys to the mind the picture which disease presents, palpation is a close second, since it is capable of revealing characteristics which the eye cannot see.

It has frequently occurred to the writer that in the diseases of the throat and nose palpation has to a very great degree been neglected by the general practitioner, and it is to illustrate the value of digital examination, particularly to the general practitioner, in some of these diseases that this paper is presented. Far be it from his idea to belittle by a word the value of the instruments which laryngology has placed in the hands of physicians. Should the ideas herein set forth result in making you more careful in your diagnosis, the object of the writer will have been accomplished.

The elaboration with which the armamentarium laryngologicum is described in all works on diseases of the throat and nose and the very scant attention paid to palpation by almost every writer on the subject are perhaps responsible for the belief of which the minds of physicians seem to be possessed, that inspection alone is all-sufficient to make a diagnosis of a throat disease; and should a doctor perchance determine to dabble in laryngology, he devotes himself to obtaining a good source of light, perhaps electric, a large reflector, and much apparatus; he imagines that he must make a diagnosis by looking into the throat and doesn't think of resorting to any other method. After laboriously depressing the rebellious tongue and perhaps catching a momentary glimpse of the pharynx, or perchance obtaining a reflection of the larynx in the laryngeal mirror lasting the fraction of a second, he makes his diagnosis.

It has always seemed to me that doctors have an indefinable dread of putting the index finger into the patient's throat and palpating its different regions. Not so the laryngologist, who always in a suitable case supplements his instrumental examination by a careful palpation of the parts. After thoroughly disinfecting the hand he gently introduces the index finger to the posterior pharyngeal wall, cautiously palpating the

¹ Read at the December meeting of the Society of the Alumni of Charity Hospital.

tonsils, perhaps the naso-pharyngeal space and upper larynx, feeling for certain changes which his eye has led him to suspect.

Let us consider for a moment which changes, generally speaking, are perceptible to the eye and which to the tactile sense.

We can see a change in conformation, as, for instance, enlarged tonsils, tuberculous swelling of the epiglottis or arytenoid cartilages. We can feel with the index finger whether the tonsil be hard, containing dense organized connective tissue, or soft and made up of granulation or lymphoid tissue; and are thus enabled to decide which method of abscission to follow, whether by the guillotine, cautery, or cold snare, the danger from hemorrhage being greater in connective-tissue tonsils after the cutting operation than after the snare or cautery loop; while in the case of soft tonsils the cutting operation is almost entirely devoid of the danger of hemorrhage.

Again, the eye detects a swelling running along the border of the posterior faucial pillar: the index finger will feel that this swelling is hard and unyielding, indicating the diagnosis of possible incipient malignant disease. Implication of the submaxillary or cervical lymphatics, discoverable by palpation, makes the surmise a certainty.

While a tense, glazed, protuberant swelling seen upon the posterior pharyngeal wall of a child leads to the supposition of retropharyngeal abscess, the detection of fluctuation by the index finger leaves no room for doubt as to the diagnosis.

The strict rules of asepsis, about which so much has of late been written, must of course be rigidly observed before the finger is introduced into the mouth. Especial attention should be paid to the index finger nail, that it be thoroughly brushed and disinfected. I cannot join in the advice of "Old Peter Krukenberg," who, according to Niemeyer, advised his pupils always to keep a long sharpened nail on the right index finger, so that, should they ever detect with the terminal phalanx the fluctuating swelling of a retropharyngeal abscess, they would need lose no time in looking for instruments, but could immediately without withdrawing the finger plunge this natural lancet into the abscess and evacuate it of its contents. Not a word about asepsis in those good old days! *Tempora mutantur*. And still I am compelled to yield to "Old Peter" his due meed of praise, for he evidently was a competent diagnostician and believed in the efficacy of digital examination in the diagnosis and treatment of retropharyngeal abscess.¹

As above stated, thorough cleanliness is the first requisite to a proper digital examination of the throat; the second is gentleness of manipulation, so that no lesion, in addition to the one already existing, may be produced; the third is a thorough knowledge of the normal topography and feel of the parts, which can only be acquired by experience in this mode of examination, and which every physician should acquire.

Let us now consider, seriatim, some of the disease conditions in which digital examination is important, if not indispensable.

Adenoid Vegetations.—The patient presents all the signs and symptoms of interference with nasal respiration, is a mouth breather, snores while asleep, has difficulty in pronouncing labials, and his chest development is retarded. Inspection may reveal hypertrophied tonsils, hypertrophic rhinitis, deflection of the septum, or mucous polypi. The child's resistance makes a rhinoscopic examination impossible or unsatisfactory. Absolute certainty and accuracy of diagnosis as to the existence of the adenoids, as to their nature, density, distribution, and localization can only be reached by introducing the index finger into the

naso-pharynx and carefully and firmly palpating the entire region. If the mass be soft, pulpy, and easily crushed, it may perhaps be removed by crushing and scraping with the finger nail at the time of examination without withdrawing the finger; when the tip of the finger feels that the vault of the naso-pharynx is roomy, its lining membrane smooth and thin, the choanæ accessible to the finger tip, the space can confidently be said to be cleared out just as well at times and better than could have been accomplished in some instances with instruments. Guye, of Amsterdam, has advocated this method of removal of adenoids altogether to the exclusion of instruments. Of course this view is extreme, inasmuch as when the growths are hard or voluminous it is impossible to remove them thoroughly without recourse to cutting instruments. Harrison Allen also, in "Keating's Handbook," "Diseases of Children," advocates the removal of adenoids by scraping and crushing with the finger.

But even when adenoids are removed by the Hooper forceps or by Gottstein's curette, a careful exploration of the naso-pharynx with the index finger is absolutely necessary to ascertain whether any small granulations be left behind, and if so to crush and scrape them away with the finger nail.

If the child be enveloped in a strong band of towel-ling imprisoning both upper extremities and be held sitting upright upon the lap of a strong nurse, the Denhard mouthgag introduced, the entire operation can be completed in a few moments, with or without instruments and without anaesthesia. Naturally under anaesthesia, the child being perfectly under control, a more thorough operation can be done.

Malignant Disease.—The diagnosis of malignant disease of the throat in its later stages can readily be made. The patient himself frequently directs the physician's attention to the growth, because of his subjective symptoms. But in incipient malignant disease, before any marked subjective symptoms are present and the eye of the examiner detects nothing perhaps except a linear hypertrophy along the tonsil or some enlargement of this structure, careful palpation with the index finger will detect induration, which at once raises the question of malignancy. The swollen lymphatics lend color to this belief, and the microscope settles the diagnosis. It has frequently happened in my experience that general practitioners have treated as cases of simple chronic pharyngitis patients suffering from incipient malignant disease. The simple method of examination by palpation, which certainly does not require the skill of the specialist, would have enabled them to make the diagnosis and would have saved them considerable reputation.

Follicular Tonsillitis, Suppurative Folliculitis, Abscess in or behind the Tonsil.—One or both tonsils are seen to be swollen and reddened. They may be studded with white or grayish patches, indicating plugging of the mouths of follicles and retention of their cheesy secretion, leading to inflammatory processes; or, on the other hand, no white or grayish spots may be visible. In either case rigors, a temperature sometimes as high as 105° F., and decided symptoms of a severe infection are present.

I have known physicians to diagnose diphtheria when these spots were visible in the throat; and when no spots were to be seen, the symptoms above described being present, the diagnosis of malaria or beginning typhoid has often been made.

The gentle introduction of the thoroughly cleansed index finger up to the anterior faucial pillar, bringing gentle pressure to bear upon the tonsil, will frequently cause the cheesy plugs or retained pus to emerge from the affected tonsil, and the diagnosis is made. Sometimes the suppuration is retrotonsillar, the tonsil being pushed out toward the median line;

¹ Niemeyer, 1875, p. 459.

the soft palate on the affected side may be swollen or protuberant, hanging lower than the unaffected side, producing asymmetry. Gentle pressure upon the swelling detects fluctuation perhaps, or it may even succeed in making pus emerge from behind the tonsil. Should this not occur, an incision with the long pharyngeal bistoury relieves the patient. We all know how much disturbance these apparently insignificant retention abscesses can cause—severe pains in the back and limbs, anorexia, prostration; in short, the symptoms of a high fever are presented. An early diagnosis, which is possible only if the finger palpates the swelling, saves much suffering.

Foreign Bodies.—It frequently happens that a small piece of fishbone, a needle, or other foreign body is embedded in the tonsil, in the naso-pharynx, or in the neighborhood of the laryngeal aperture, *i.e.* in the vallecule, arytenoid cartilages, aryepiglottic folds, etc. The eye detects the small foreign body with the greatest difficulty, perhaps not at all. The patient complains that it is there nevertheless—he feels it pricking him. The index finger, gliding gently along the tonsil, is introduced into the upper larynx or naso-pharynx, and may suddenly feel the sharp point of the needle or fishbone protruding from the mucous membrane, and serves as a guide for the passage of forceps for the removal of the same. Gottstein¹ recommends palpation of the interior of the larynx in children for the diagnosis of disease of the epiglottis or aryepiglottic folds, and also of foreign bodies.

Intubation for stenosis of the larynx from whatever cause becomes a simple operation if the physician possess the *tactus eruditus* as applied to the throat. The child is held sitting upright in the proper position, the gag introduced; the physician's left index finger glides along the base of the tongue until the epiglottis is reached. Immediately behind this is felt the entrance to the larynx, into which, the finger acting as a guide, the tube is slipped with the greatest ease.

In diseases of the nose the tactile sense has not such a wide field of application.

I remember a case of rhinolith, however, which the index finger succeeded in dislodging and removing after all instruments had failed to do so. It was the case of an old lady from whose nose Dr. L. Weiss, of this city, had been trying for a long time to remove a large, hard, round rhinolith, of perhaps twenty years' growth. It had worn out a concave bed for itself in the osseous floor of the nose, and so completely and exactly did it fill out this concavity and the nares that it eluded every attempt to grasp it with forceps or any other instrument. It revolved in the concavity as easily as a ball does in its socket. The discharge from the nose was fetid and hemorrhage was the result of the prolonged attempts at removal. After myself trying the forceps for a time I gave it up in despair; but noticing the marked dilatation of the nostril and of the nasal passage, I introduced my index finger and patiently dilated, pushing the finger slowly forward. It required quite a little time, but the stone was finally reached and by degrees was pushed out of its bed toward the posterior nares. Finally I had it so near this opening that, introducing the first two fingers of the left hand into the naso-pharynx, I pushed the stone through the choana and with the two fingers in the naso-pharynx grasped it. Of course atrophy of the mucous membrane and the marked enlargement of the nares were features of this case favorable to digital dislodgement of the stone. The case illustrates, however, one of the extraordinary uses which the index finger can serve in diseases of the nose.

In the Asch operation for deflection of the septum, after the crucial incision into the septum has been made, the index finger is introduced into the nar-

rower nostril and the fractured septum is pushed toward the median line until it is straightened as much as possible, after which the splints, cork or otherwise, are introduced.

The writer is aware that nothing new has been stated in this paper, nor does he desire to underrate to the slightest degree the value of instrumental examination in the domain of laryngology; but if he has impressed upon the mind of a single colleague the importance of digital examination as an additional help in diagnosis, of the value of the *tactus eruditus* in this class of diseases, of the ease and simplicity of this manipulation, and finally, if his words carry conviction, his object will have been accomplished.

805 MADISON AVENUE.

PSYCHICAL INFECTION: REMARKS UPON THE PROBABILITY OF A MENTAL CONTAGIUM.¹

BY HENRY S. STARK, A.M., M.D.,

NEW YORK.

WHILE it is no part of my purpose to enter into an elaborate discussion of the pathology of the mind, but rather to call attention to that particular phase of it which furnishes the subject-matter of this paper, nevertheless such a work would be much to be desired; for I find after a careful survey of the literature of the subject that there is no contribution on mental pathology which can be styled, according to newspaper phraseology, *fin-de-siècle*, that is, up to date, or one that covers the entire ground.

In this ultra-bacteriological era it should occasion no surprise that so many new fields of speculation and study should be constantly opened up, for this theory of infection is rapidly assuming such proportions that we cannot ignore its influence on medical thought any longer. Glance at the trend of recent medical activities, of present investigations, and the conclusion is forced upon us that the theory of infection is playing the leading rôle. Scarcely a generation since Lister, Schwann, Tyndall, and Pasteur startled the scientific world with their discoveries, and yet the whole gamut of the medical sciences has been revolutionized to conform to their views.

The presumption that mental or psychical infection is a possibility rests on the close analogy between mind and matter in all their operations and phenomena, from both a physiological and a psychological standpoint. Admitted that material or physical infection is and has been proven, it no longer savors of the Utopian to believe that one mind may infect another under certain favorable conditions. Under the circumstances, then, even the most sceptical will be compelled to admit its plausibility. This theory of psychical infection, although foreshadowed by the germ theory, has not yet taken on a scientific aspect, for the simple reason that systematic attention was never directed toward it. It is therefore the writer's object to focus your attention by means of this article on this psychological creation and innovation in the realms of speculative medicine, in the hope that this theory may be worked out in detail and that possibly something permanent may be the practical outcome in the way of treatment for certain diseases and anomalies of mind.

The term "psychical or mental infection" is used by me in contradistinction to material or physical infection. The two varieties are not at all incompatible: on the contrary, they are frequently coexistent.

¹ "Krankh. des Kehlkopfes," p. 43, 1890.

¹ Read at the meeting of the Section on Neurology of the New York Academy of Medicine, December 13, 1895.

In physical infection the following assumptions are inevitable, and it will be apparent that nearly the same are applicable, only in a different guise, in psychical infection:

First, there must be the infecting agent.

Second, there must be the *contagium* or *materies morbi*, so-called.

Third, there must be an infected agent.

Fourth, there must be the medium of infection.

Consider for a moment the character of these conditions, and you will admit that they can be duplicated in the psychical sphere.

First, in place of the infecting agent we have what I might properly term the conveying or objective agent. In place of the infected agent we have the passive or receptive or subjective agent. The medium of infection is the mind in all its component parts—intellect, will, judgment, etc. It is in relation to the contagium only that a bone of contention could reasonably arise. Now, the essential distinctions between mind and matter are not even to-day sufficiently understood to enable one to ascribe to each its whole range of properties and aspects. It is on this account that psychical infection is not entitled to more credit than to be called a theory. Nevertheless it by no means follows that because we cannot explain the *modus operandi* by which all the varied phenomena of mind are produced they are of doubtful existence. If that were the case, all phenomena of whatever nature that could not be accounted for at random would of necessity be relegated to the realms of scepticism, while the whole fabric of reasoning would be swept into an everlasting oblivion. There are many truths and facts in science which cannot be explained yet cannot be discredited. Time and time again the mysteries of yesterday became the revelations of to-day. Therefore, although the subtle contagious element may be the missing link in this chain of reasoning, nevertheless this theory is a justifiable one in view of our daily observations of psychical disturbances. By thus comparing the two varieties of infection in parallel columns, as it were, we have at least a working hypothesis which can be employed as a basis to demonstrate the reliability of this supposition.

The first thought that would occur to the unbeliever would be whether there was any foundation in fact for this apparently strange hypothesis. In answer I would state that the amount of evidence that could be accumulated in corroboration of this theory would take volumes to catalogue. A moment's consideration of everyday events in the psychical world would furnish the data and material for the solution of this problem. For instance, what we style imitation is only to my mind one variety of psychical infection. It is thought-transference, conscious, voluntary, or compulsory. That is to say, the exact ideas in one person's mind are reproduced in another's with the subject's sanction or through his own efforts, or, on the contrary, without his knowledge or even consent. The degree of this imitative faculty varies in different subjects and at different epochs of life. Infancy and youth are peculiarly susceptible, while old age is slightly disposed to imitation. Experience shows that the mind can be so trained as to be made entirely proof against imitation. Invulnerability seems from experience to be in direct ratio to education, intelligence, and environment. To copy and imitate is a constant weakness of the human intellect. The inclination may assert itself in single individuals or in classes and communities. Sometimes it becomes so strong as to resist all efforts of the will. At other times the infection runs riot, causing epidemics of various mental aberrations, such as suicide and insanity and other mental and nervous derangements. Certain seasons of the year and certain epochs seem also to be conducive to epidemics of

imitation. To illustrate my meaning, permit me to chronicle a few instances of mental infection through the force of imitation. It is not necessary for this purpose to appeal to ancient history, but simply to revert to current events.

A Western farmer, imbued with an extravagant idea of his own importance, confident that he is the apostle of good government, believing a change in the industrial and labor laws to be necessary, concludes to march on toward the national capital in order to petition Congress for a redress of his own grievances and those of his fellow-citizens. The novelty of the enterprise at once appeals to our lay editors, who see a brilliant opportunity to interest their patrons. Through press notices the news spreads in all directions, so that as the apostle's march progresses recruits and sympathizers are gathered by the way. The infection has spread with lightning rapidity, so that in a few days enough reinforcements have been secured to constitute a good-sized army. Many who cannot join the army lend it their financial support. Thus we have a Coxey's army—a notorious example of mental alienation due to the force of imitation abetted by sympathy.

A small band of religious enthusiasts, believing the world to be infested with enough iniquity and sacrilege to carry its occupants to the verge of despair and to a point beyond all redemption, conclude to come to the community's rescue. In order to make their efforts attractive and the movement picturesque, they resort to cymbals and tambourines, to banners, escutcheons, and uniforms. Their favorite haunt is a street corner, a square, or a country lot. The attraction is sufficiently strong to meet with the approval of many who are religiously inclined. They enlist in the cause. Soon the small band has grown from local proportions to international importance. Thus we have a Salvation Army, another illustration of psychical infection through the force of imitation.

A third and last illustration: A certain type of woman, who as a result of misfortune or through force of circumstances has lost the feminine delicacy of her sex, carrying the firm conviction in her mind that her worthy mission can best be attained by approximating man in his dress, manners, and occupations, affects his costume and possibly his inclinations. At once she sets a pace that is followed by many of her own mental build and calibre. The number who imitate her is legion, for the mind of the female is notoriously flexible and impressionable. Thus we have the "New Woman," another recent example of mind poisoning. Other examples, such as the bicycle or roller-skating crazes, could be mentioned, but why weary the reader?

Besides psychical anomalies there are a few nervous disorders of a functional character that may be acquired by imitation. Thus we are familiar with epidemics of chorea, hysteria, and neurasthenia that have their origin in schools, boarding-houses, and seminaries.

Another interesting variety of psychical infection and one which is at present absorbing the attention of alienist and physician is hypnosis or suggestion. Here is a comparatively unknown force, power, magnetism, or what not, which we know by its phenomena alone, just as we know matter by its properties alone. Ever since Mesmer at the close of the eighteenth century first announced his celebrated doctrine until to-day, no satisfactory explanation has been offered for this psychological mystery. Numerous attempts have been made by writers of distinction to explain the hypnotic state upon a physiological basis; that is, to attribute this induced state to a disturbed function of the central nervous apparatus. These efforts never survived the tests of time and experience, the consensus of present opinion being that such conclusions were based on mistaken premises and were unacceptable in

the light of recent experiences and scientific investigations. Besides this explanation there were others equally original and equally untenable. There were theories galore, so numerous and diverse as to gratify even the most whimsical. None of them, however, was based on the most plausible of all theories, the theory of infection. I know of no better explanation for this strange psychical phenomenon than to call it a mental infection. The grounds for such a belief would be furnished by the evidence based on numerous instances and upon the psychical experiences of the hypnotized. Consider for a moment the nature, the method of procedure, the results, the sequence of events in a given case, and the inevitable logic of it all is that one mind is infecting another, whether for good or for evil, whether with the subject's knowledge and consent or not it matters not; suffice it to say, it is a direct transmission or emanation from an active to a passive agent of a subtle, psychical contagium. Take the familiar instance of a hypnotic séance. The *opérateur* wills that the receptive subject shall become possessed of certain feelings and emotions, or that he shall perform a definite act. The infection is carried to the subject by a few strokes or passes or through the agency of a brilliant fixed body held in his line of vision. Directly the subject becomes the tool of the operator's will. The psychosis has passed from one to the other without any physical exertion on the part of either, and is known to us only by the expressions in the hypnotized subject. Even the analogy alluded to in the beginning of this article, namely, that which obtains between physical and psychical infection, still holds true, for in place of infected blood, tissues, or organs, we are now dealing with an infection of the will, of the intellect, or of the emotions. While in physical infection the channels for the entrance and transmission of the microbic element is either the blood or the lymphatics, in psychical infection the portal is either the reason or one or more of the special senses.

If this theory of psychical infection should be generally accepted as a reasonable explanation for the hypnotic state, we would be in a position to understand those strange and phenomenal instances of mind controlling and mastering mind which from time to time are chronicled in the columns of the lay press. We could then comprehend how men, especially those neurotic degenerates with plastic minds, can become the willing prey of others to such a degree as to lose their distinct personality and their own idea of self. We could also interpret and account for those cures, apparent or real, from diseases of a hysterical origin which have been wrought at the well-known shrines and during times of religious revivals and which savor of the miraculous to the laity. The bare mention of these facts will serve to recall familiar instances. In like manner this theory of infection could be employed to account on a scientific basis for that psychological complex termed "personal magnetism," examples of which we encounter in our daily experiences. We would likewise come in possession of a scientific explanation for the metaphorical expression, "to poison the mind." It would determine once for all that hypnosis in any or all of its phases is a pathological process depending for its origin on contagium probably specific in character, although unrecognizable by any of the five special senses.

Granted that the psychical processes cited—namely, imitation and suggestion—are types of psychical infection, that is to say, they owe their origin to a mental contagium, it will be apparent at once that this infection must be of unusually frequent occurrence and must assert itself under varying degrees of virulence and intensity. This assertion is in no sense an exaggeration, but is borne out by our daily experiences.

Another point of interest and one that again illustrates the parallelism between psychical and physical infection is the perfect immunity enjoyed by some fortunate individuals and the extreme susceptibility to this poison that others exhibit when brought within the pale of its influence. Thus a person of strong will, of forcible character, and of high intellectual power cannot against his will or wish be brought under the hypnotic influence despite the most strenuous efforts at mental coercion. On the other hand, a fickle, impressionable, vacillating mind loses its self-control readily when brought under the influence of a psychical contagium. These are matters of great importance from a medico-legal standpoint, as they enter largely into the consideration of the question of mental responsibility for crime and the question of hypnosis as a defence to the charge of crime. Recent criminal dramas enacted in this city have brought this matter into unusual prominence, and point to the necessity and advisability of consulting an expert in psychology in criminal cases involving psychical phenomena.

I have thus attempted within the narrow scope of a short paper to direct your attention into certain channels of thought with a view of having others follow in the same direction. If I have succeeded I shall feel that I have accomplished all that I intended.

270 EAST SEVENTH STREET.

Progress of Medical Science.

Micro-Organisms in the Blood of Scarlatina.—Dr. Crajkowski secured blood from scarlatina patients by a needle prick of the ear, and from it made cultures and cover-glass preparations (*University Medical Magazine*). The culture media used were glycerin agar, agar with hamatogen, blood serum, gelatin, bouillon, serous transudate from the peritoneum and from the tunica vaginalis testis. The cover-glass specimens were dried, fixed, and stained in Chencinski's mixture. These specimens showed micro-organisms in the form of diplococci. They were found in relatively small numbers—one or two in a field of vision—and generally occurred singly, though sometimes in twos or short chains. They were never seen in the blood corpuscles. The shape of the individual was oval, though with ordinary magnification no difference between the diameters could be observed. They were not stained by ordinary methods and decolorized readily when stained by Gram's method. The specimen from fresh blood had a surrounding capsule which was absent in the dried form. The growth of the organisms on culture media was carefully studied. Upon the solid culture media it was very slow. Upon all the solid media the colonies appeared under the microscope as minute dewdrop-like points measuring one-half by one-half millimetre and not becoming confluent for months. The organisms continued vital upon the solid media for from three to four months if protected from drying. In liquid culture media, especially in bouillon, the organisms formed a yellowish-white, finely granular, light precipitate at the bottom of the glass. The inoculation of the organisms beneath the skin and into the blood of rabbits was without result. Inoculated mice died in three days with the cocci distributed through the blood.

Function of the Prostate.—C. Mansell Moulin (*Journal of Anat. and Phys.*) has revived the old doctrine that the prostate has nothing to do with micturition and has only secondary connection with the urethra. He claims that its function is to add certain constituents to the seminal fluid which serve to arouse and maintain the vitality of the spermatozoa.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, April 18, 1896.

MORBIFIC AND INFECTIOUS MILK.

THROUGH the kindness of Dr. G. M. Kober¹ we have received advance sheets of this report to the health officer of Washington.

It is a thorough and most important piece of work, the authors reviewing the entire subject and adding the most complete bibliography yet published.

The conclusions drawn by the authors are of the greatest interest and of vital importance to the general public.

When we recall, say the authors, the many ways by which milk may acquire morbid properties, we see the necessity for the proper protection of the public by placing dairies, the herds, and the milk market under a strict sanitary control. The owner of a dairy should be required to subject his stock to frequent inspection by a competent veterinarian, and all animals found to be suffering from diseases like tuberculosis, erysipelas, anthrax, pleuropneumonia, foot-and-mouth disease, septic and other fevers, specific enteritis and other intestinal disorders, rabies, tetanus, garget and other inflammatory conditions of the teats and udder; and also those animals which are being treated with medicaments for any or all causes, all of which are disqualified from producing a pure or sound milk, should be excluded. The milk of animals five days before and after parturition is likewise unfit for human consumption.

The pasturage of the animals should be looked after with the greatest care; the animals should be groomed daily, and before milking the teats and udders should be thoroughly washed with water previously boiled. The necessity for this has been repeatedly pointed out and is of special importance, since we consider the presence of excrementitious matter and fecal bacteria in milk next in danger to the presence of disease germs. The requirements of cleanliness apply with equal force as to the milkmen and as to their persons and clothing, and they should be requested to keep their fingernails free from dirt and to make a careful toilet just before milking. All persons engaged in handling the milk should be free from disease. No family ever thinks of employing or keeping a cook afflicted with a communicable disease, and yet not the

slightest restriction is placed upon, nor a question asked about, the persons who handle our milk supply, which we know affords an excellent culture medium for disease germs.

A most excellent suggestion of the authors is that the products of each ten cows should be mixed, not only to insure uniformity but also to diminish the danger of transmitting disease germs in concentrated doses from any one animal.

Absolute cleanliness, of course, should be observed in transferring and bottling the milk, and the retailer should be duly registered and be required to furnish the health officer with a list of customers. These lists should be arranged at that office on the "index-card system," so that the simultaneous occurrence of infectious diseases in a number of families supplied by the same milkman may be promptly discovered and the mischief checked.

On the subject of "Milk Standards" the authors conclude, after an examination of the best data on the subject, that we have a right to expect a milk containing 12.52 per cent. of total solids, composed of 8.75 per cent. non-fatty solids and 3.75 per cent. fat, and also that the legal standards should be modified accordingly.

The official standards in force vary from 13 to 12 per cent.; it seems to us that the standard should be at least 13 per cent., as in Massachusetts.

The authors go on to say that while it would be manifestly unjust to condemn a milk as adulterated when it has more than 87.5 per cent. water, on the other hand the adoption of a minimum standard would result in the sale of a very large quantity of adulterated milk, which, apart from diminishing the nutritive value of the milk—a matter of great importance in infant-feeding—is often the immediate cause of transmitting disease germs by the addition of infected water. In the opinion of the writers all this can be prevented and milk of uniform standards can be obtained by encouraging the establishment of milk depots like the Walker-Gordon laboratory of Boston. In the management of this establishment farm and herd are under the absolute control of the laboratory, and are used for laboratory purposes only; the cows, their food, their stables, their pasture, and their drinking-water are subjected to the frequent, paid, critical examination of the best veterinary surgeon that can be procured in Boston. The dairymen dress in white suits before milking, each having previously had a bath. The cows are milked into glass pails, and the milk, after being aerated and cooled to about 44° F. in a tank of ice and water, is delivered at the laboratory in Boston within four hours of the milking.

At the laboratory a ventilating engine keeps up a constant change of air, and a hose keeps the enamelled brick walls and stone floors wet to prevent any remaining dust from contaminating the milk while it is being "modified." The whole milk, after being "Pasteurized," passes through a Stockholm separator which makes sixty-eight hundred revolutions a minute, yielding a cream of an almost constant sixteen per cent. fat. It not only does this, but it removes all dirt that from unavoidable causes has gained access to the

¹ "Report on Morbid and Infectious Milk," S. C. Busey, M.D., and G. M. Kober, M.D., Washington, D. C.

milk, thus yielding a clean, skimmed milk, practically free from fat (only 0.13 per cent. remaining).

Such milk laboratories would accomplish the following objects:

(1) The source of the original milk would be closely controlled.

(2) The producer would be paid according to the quality of the milk.

(3) The milk would be Pasteurized before it reached the consumer.

(4) The milk would be sold under uniform standards of "full" and "skimmed" milk, and its sale perfectly controlled by the sanitary authorities.

(5) The milk could be modified in the laboratory according to the wishes of the consumer, and for invalids and bottle-fed children according to the formula of physicians, with a justice and accuracy not possible by any other method.

(6) Condensed milk preserved in glass bottles is a special necessity during the prevalence of blizzards or other interruption of the milk traffic, also upon long journeys; and, since a higher standard than the present is demanded for correct infant-feeding, the milk could be modified by the addition of sugar of milk and thus form the best possible basis for condensed milk of a proper standard.

Finally, we sincerely trust that this excellent report will cause an immediate and widespread agitation throughout America for proper legislation as to the milk supply and the establishment of "milk laboratories" and of milk-cattle inspection.

We really owe Drs. Kober and Busey a debt of gratitude for this work.

DOCTORS BEGINNING TO MAKE THEIR INFLUENCE FELT.

TIME was when a physician practised physics and was known by his good works of a professional nature. To judge by what one reads in the daily press, this good old custom is fast giving way to habits of gaining renown by exploits wholly foreign to medicine. In the same week we read that "Doctor" A— takes many of the Boston horse-show prizes, and "Doctor" B— allows himself to be worsted by a Boston prize-fighter, while "Doctor" C— superintends a private scrap in his down-town barroom, known as "The Doctor," which results in the death of one of the contestants. Then comes along "Doc" McLean with his thoroughbred Berclair and wins the Derby. But best of all is the story of the burglar who tried to rob a physician in East Eighty-Fourth Street. Most assuredly the profession has advanced. Formerly it was the lawyer, the plumber, or the ice man who was complimented in this way by the burgling fraternity. The doctor had in his office a safe. Another sure sign of progress, but a habit to be deprecated as tending to attract outside physicians to the metropolis. However, the safe was there and the doctor found a man working at the lock. The latter explained his presence by a plea of feeling unwell and desiring medical advice. The doctor percussed his chest, and it is acknowledged by the thief, now in custody, that the per-

cussor was applied more vigorously than he thought the urgency of his case required. The doctor then wrote a prescription and charged a fee of \$5, spot cash, which he immediately placed within the safe, just as an angler puts a fish bait upon his hook, reset the combination, and retired to watch for further prey.

With gossips busy telling how a doctor of one variety has just stolen a sermon in New York, and how a doctor of another kind has embezzled from an order of United Friends in Poughkeepsie, it is refreshing to read that one of our own ilk has held up a bold, bad burglar and given him a dose of his own medicine.

A PHYSICIAN'S HEROISM.

WE read in the *British Medical Journal* that Dr. Ernest Helby saved a child's life at Croyden Fever Hospital by sucking the diphtheritic membrane from its throat after tracheotomy had been performed. The doctor contracted the disease and for some time his life was in danger. He finally recovered under antitoxin treatment. We scarcely know whether such action is worthy of praise or blame. We become so accustomed to universal selfishness that the discovery of a hero comes as something of a surprise. The highest type of self-sacrifice, the willingness to risk one's own life for that of another, cannot fail to call forth our highest admiration. However, such instances as this—the results are not always as felicitous—raise a question in casuistry. Is not the life risked or sacrificed worth more to humanity than the life saved? Is it right for a physician to risk sacrificing those dependent upon him? We would not be chary of praise, but we suggest that the necessity of such risk must be decided by the individuals personally concerned.

News of the Week.

A Death Alleged to be Due to Diphtheria Antitoxin.

—An infant son of Privat-Dozent Langerhans, professor of the City Hospital (Moabit), Berlin, died suddenly last week after receiving an injection of diphtheria antitoxin. The inoculation was made as a precautionary measure, a housemaid in the family being at the time ill with diphtheria. The father attributed his child's death to the serum, and caused the following notice to be published conspicuously in the Berlin papers for several days: "Our darling Ernest, aged twenty-one months, died suddenly in perfect health in consequence of an injection of Dr. Behring's diphtheria serum." Naturally this has given rise to much discussion among the physicians and in the press. The authorities at once seized the body of the child and caused an autopsy to be made. The result was wholly negative, and nothing was found to prove or disprove the charge of Dr. Langerhans. Dr. Asch, writing in the *Vossische Zeitung*, gives instances of similar cases, one of them relating to the daughter of a high Prussian medical official, who was inoculated with Dr. Behring's serum and was in consequence ill for three months. On the other side, Professor Brieger

expresses the opinion that it is a serious mistake to draw the deduction from an unexplained case that the serum is dangerous, and asserts that a normal injection of the serum will not cause death.

Cartwright Lectures.—The third of the series of the Cartwright lectures of the College of Physicians and Surgeons will be given in the hall of the Academy of Medicine, No. 17 West 43d Street, New York, on Wednesday, 22d, at 8:15 P.M., by George S. Huntington, A.M., M.D., professor of anatomy in Columbia University. The subject will be: "Morphology of the Bronchial System and its Relation to the Pulmonary Vascular Supply in Mammalia."

Prof. Mariano Semmola, of the University of Naples, is dangerously ill. He had a cerebral hemorrhage on March 28th, and it is feared that he will never recover sufficiently to resume his professional labors.

Dr. Franz Vulliet, professor of gynecology and obstetrics at the University of Geneva, died on March 20th. He was president-elect of the International Congress of Gynecology and Obstetrics, which is to be held in Geneva during the coming September.

Antitoxin Treatment of Diphtheria in Private Practice.—The committee of the American Pediatric Society to which this matter has been referred desires to place before the profession, for collective investigation, the subject of "Antitoxin Treatment of Diphtheria," the cases for the investigation to be collected entirely outside of hospital practice and published as the report of the society. Two points are to be made prominent: First, the length of time elapsing between the first appearance of the disease and the administration of the serum antitoxin. This is to be stated as accurately as possible, even to fractions of a day. Second, the severity of the disease, as shown by (a) extent of membrane, (b) general prostration, (c) involvement of the larynx. As every one knows, bare figures may in no way adequately express the full facts; remarks are therefore called for, and it is hoped the contributors will give fully their impressions. A diphtheria case under antitoxin may do very well and yet the physician reflect at the end that it was one which might be expected to recover under any form of treatment. On the other hand, one requiring intubation may recover promptly and without even becoming much prostrated. It is thought that family practice offers the only fair test of the efficacy of serum antitoxin treatment and that the most trustworthy statistics must be gathered from that source. In these investigations it is desired to bring together facts and opinions from cases which have what may be called a fair chance of demonstrating whether antitoxin accomplishes in the human body what experimentally it has been found to do with uniformity in animals. The co-operation of members of the profession is invited in this investigation, in return for which the society will mail to each contributor the full report when it is published. It is desired, even if a physician has but one case, that he will communicate his observations bearing upon the following points: Age, condition at

time of injection, time from initiative symptoms to that of injection, number of injections, whether or not diagnosis was confirmed by culture, extent of membranous deposit, whether or not intubation or tracheotomy was performed, and a description of sequelæ. In this way much valuable data can be obtained not otherwise available. Reports should be directed to Dr. Joseph O'Dwyer, 967 Lexington Avenue, New York.

Cholera in Egypt.—Cholera has appeared at Alexandria. Several natives and an English merchant have died of the disease.

Maryland State Board of Health.—Dr. S. Chase de Krafft, of Cambridge, Md., has been appointed a member of the health board of that State.

American Laryngological, Rhinological, and Otolological Society.—The second annual meeting will be held in New York City, April 17th and 18th. A large number of practical papers will be presented and a universally profitable time is anticipated.

No Pay, No Work.—It has been decided by the Supreme Court of Illinois that the health authorities have no right to require physicians to report contagious diseases or births without remuneration. It is a nice question whether the physician, whose aim is the prevention as well as the cure of disease, is not morally bound to warn the community of danger when this can be done at a not unreasonable expenditure of time and labor. At the same time it is unjust on the part of the community to compel him to do so and even to force him under pain of imprisonment or a fine to pay for the postage on such notification. Of course, the State cannot afford to pay a large fee for such service and neither would physicians demand it, but it would seem as though a compromise might be affected whereby the physician would receive twenty-five cents for each notification of a case of infectious disease or a birth. Such a plan is, or was, in existence in Connecticut, and we believe worked satisfactorily to both the State and its medical benefactors.

New Journals in Texas.—The *Southwestern Medical Record* is a new namesake established in Houston, and the *University Medical Journal* is a new monthly published in Galveston under the auspices of the Medical Faculty of the University of Texas.

The American Medical Association—What Is It?—A correspondent asks for information as follows: "I see that the American Medical Association will meet in Atlanta soon. Can you give me any data on the subject or refer this to any one who can—how large a society is it, date and place of meeting? I am especially interested in Jenner and vaccination, and I would like to present some matter to the society, if it is a large society and worthy the effort."

Philadelphia County Medical Society.—At the meeting of the Philadelphia County Medical Society on April 8th, Dr. A. V. Meigs read a paper on "Infant-Feeding," in which he renewed the conclusion, reached by him many years ago as a result of an analytic investigation, that mothers' milk contains, as a rule,

not more than one per cent. of casein, and that in the construction of a substitute this important fact must be constantly borne in mind. He also maintained that human milk is very constant in constitution, so that, once the proportions of its constituent elements are accurately and definitely determined, no variation need be made during the period of the employ of the artificial substitute. Dr. Alfred Stengel read a paper on "The Treatment of Pernicious Anæmia," in which he supported the view that the disease is essentially a hæmolytic one and to be viewed as a secondary anæmia, although often the causative condition may escape detection. Among the remedies from which the most good may be expected are arsenic, which has been viewed as a specific and which probably acts by an influence on hæmogenesis; iron, which is most useful in convalescence; and bone marrow, which has proved efficacious in some instances and perfectly futile in others. As contributory therapeutic measures aiding in the better distribution of the blood-corpuscles may be regarded massage and infusions of blood or physiologic solution into the vessels or subcutaneous tissues. The matters of diet and hygiene also must receive careful consideration. Often apparent cures are followed by relapses.

The Southern Medical College in Atlanta graduated a class of eleven on the evening of March 30th.

Pathological Society of Philadelphia.—At a meeting of the Pathological Society of Philadelphia, held on April 9th, Dr. J. P. C. Griffith presented the liver from a patient manifesting during life symptoms of acute yellow atrophy, diminished area of hepatic percussion dulness, leucin and tyrosin in the urine, jaundice, delirium, coma, with signs of concomitant nephritis. Upon post-mortem examination the liver was found greatly reduced in size, but histologic sections disclosed free round-cell infiltration, with less acute degeneration than was anticipated. Dr. Judson Daland showed the dilated heart of a patient who had died of pernicious anæmia; it presented an abnormal muscular band stretched across the cavity of the left ventricle, which was not recognized during life. Dr. C. W. Burr presented three brain tumors, one of which, arising from the membranes and merely displacing the brain substance, could readily have been removed had it been diagnosed. Dr. Joseph Sailor showed an infiltrated suprarenal capsule from a case in which metastasis had followed amputation of a carcinomatous breast without recurrence in the original seat of disease. Other than the involvement of the suprarenal bodies there was no obvious adequate cause for death, which, it was suggested, might have been due to the obliteration of the parenchyma of these bodies, with the attendant loss of function. Dr. W. E. Hughes showed the spleen of a patient who had died of typhoid fever; it contained an abscess and several infarcts. Dr. F. A. Packard presented a heart with a polypoid tumor arising from the tricuspid valve and also an encapsulated new formation of the liver resembling an hydatid cyst. Dr. F. S. Pearce demonstrated the greatly thickened skull cap from a case probably of osteitis deformans. Dr. Alfred Stengel showed a specimen from a young

man of colloid carcinoma of the rectum with widespread extension, evidently by contiguity but without apparent metastasis.

The Health Officer of Atlantic City, N. J., is now a physician, Dr. Walter Reynolds having recently been appointed to that office by the local board of health.

A New Hospital in Plainfield.—It is proposed to establish a homœopathic hospital in Plainfield, N. J. The practitioners of that faith complain that they are not permitted to treat their own patients in the Muhlenburg Hospital of that city.

Alleged Infection of Glanders by Canadian Horses.—A committee of the health board of Liverpool, which has been making inquiries into the subject, alleges that the spread of glanders among horses in that city is due to the importation of Canadian horses. The committee is about to send a deputation to the board of agriculture to urge the government to take restrictive action upon the importation of such animals. The allegations of the Liverpool committee are emphatically denied, however, by the Canadian officials.

"The Profession in Need of Money" is the title of an article in the *American Medical Journal*. The condition exists and we fear always will exist, but it can hardly be removed by protesting that fifty cents in silver equal one hundred in gold, as the writer of the article would have us believe.

An International Homœopathic Congress is to be held in London during the week ending August 8th. The president of the congress is Dr. Pope.

Backache.—It has never been in evidence why a woman's backache should generally be attributed to pelvic disease. Men have backaches and they are not uniformly attributed to genito-urinary trouble. It seems that the practitioner might treat the owner of a backache as a patient, not as a woman.—*Kansas City Medical Index*.

Obituary Notes.—DR. J. A. MURPHY died at Wilkesbarre, Pa., on April 4th, at the age of fifty-four years.—DR. JOHN STERLING died at Philadelphia on April 4th, at the age of sixty-five years. He was born in Ireland, but came to this country in early life, graduating from the medical department of the University of Pennsylvania in 1856. He served a term as resident physician in the Pennsylvania Hospital and during the war was a member of the medical corps that manned one of the receiving stations for sick and wounded soldiers in Philadelphia.

Dr. J. E. Schadle, of St. Paul, has been appointed instructor in clinical laryngology in the medical department of the University of Minnesota.

Antitoxin in Philadelphia.—The Philadelphia Board of Health has placed at the disposal of the physicians of that city the surplus antitoxin of diphtheria prepared in the municipal bacteriological laboratory for use in indigent cases, provided a report of the results and a history of the case are furnished in return.

An Aged Ball Player.—A man named Baugh, living in Indiana, recently broke his arm while playing baseball, but recovered in time to celebrate his one hundred and seventh birthday.

Miss A. I. de Steiger, a medical woman of London, was recently appointed third medical officer to the Essex County Lunatic Asylum, Brentwood. In order to make the appointment of a woman to this office regular it was necessary to alter the rules. England is coming on despite the fact that her two leading universities still refuse to confer degrees upon women.

Lyssophobia.—A girl of eighteen years, possessed of a nervous temperament and with neurotic antecedents, has been suffering at Lyons, N. J., with symptoms of hydrophobia, although never having been bitten by a dog. This condition is very rare, though well recognized as a groundless fear occurring in hypochondriacs.

Cremation in England.—A crematory is being erected at Liverpool, making the third in England. The others are at Manchester and at Woking; there is also one at Glasgow. Woking had 150 cremations in 1895, making its total number 733.

The Evils of Bakeshops.—At a meeting of the Ladies' Health Protection Society held recently, Mr. Thimme, editor of the *Bakers' Journal*, read by invitation a paper on "The Evils of Bakeshops," in which he said that there were two thousand bakeries in this city, most of which were located in cellars that had never been originally intended for such use, and they were not only badly ventilated but were the favorite haunts of cockroaches, spiders, mice, and even rats. Coal dust and other matter floated around the places, making them unhealthy as workshops and rendering it altogether impossible that wholesome bread could be produced under such conditions. Bakeshops were often the sleeping-places of the employees, and were not more than six feet from floor to ceiling. As an evidence of the danger of such places, the speaker said that some samples of bread from these bakeshops had been found to contain thirteen varieties of living micro-organisms. In case of contagious disease among the occupants of these cellars, there was no reason why the elements of contagion might not be distributed broadcast through the city in the bread there baked.

The Rush Monument Fund.—Since the first of the present year the amount of new subscriptions received for the Rush monument fund has been \$281, making the total amount now on hand \$3,729.39.

The Nebraska State Medical Society will hold its annual meeting at Lincoln on May 19th, 20th, and 21st. The titles of all papers and the names of prospective new members should be sent as early as possible to the secretary, Dr. George Wilkinson, Kasbach Building, Omaha.

Volunteer Patients.—True politeness consists essentially in a desire to give pleasure to others, and nowhere else is this most engaging of traits better exemplified than in the south of France. When Presi-

dent Faure stopped at Arles on his recent tour and said he would inspect the hospital there the authorities were dismayed, as there were no patients. As they did not wish to disappoint the worthy head of the republic, however, they sent out a call for volunteers, and when the president appeared he found all the beds occupied by convalescents.

The Vermont Healer, Bradley Newell, the blacksmith, has arrived in Boston. Now for a season we may expect that the hitherto excellent business of the Hub clairvoyants, faith curers, and the numerous body of "scientific" healers in general will suffer a reverse. The Hub is admittedly a great city, but how its citizens do love the occult!

Cork Nurses bob up serenely and refuse to take lodge and society cases under those physicians who attend the patients at contract rates, preferring to nurse only under those who maintain proper professional dignity.

Orange Memorial Hospital.—Mr. Frederick M. Shepard has donated \$10,000 for the construction of a pavilion for consumptives to the Orange Memorial Hospital.

The Association of Military Surgeons of the United States.—The sixth annual meeting of the Association of Military Surgeons of the United States will convene in Philadelphia, Pa., on May 12, 13, and 14, 1896. The morning session of Tuesday will be held at the Broad Street Theatre, at ten o'clock, where addresses will be made by Governor Hastings, Mayor Warwick, General Snowden, Dr. Da Costa, and President Read; also the report of the committee of arrangement, by Chairman Maj. J. Wilks O'Neill. An interesting programme of scientific papers has been arranged to be read and discussed during the day sessions. The evenings will be given up to pleasure, which has been amply and generously provided for by the committee of arrangements in the manner of receptions, social entertainments, etc. On Tuesday afternoon, at three o'clock promptly, at Hotel Walton, the regular business session will begin, with reports of committees and reading of papers. On Thursday morning and afternoon the business session and reading of papers will be resumed at Hotel Walton. The registration committee will have headquarters at Hotel Walton, and members are urged to be enrolled as soon after arrival as possible.

A Layman's Opinion on London Medical Students.—The ignorance and unskilfulness of the average English practitioner as turned out of the medical colleges are something appalling. I have attended two or three clinics in the principal London hospitals for the purpose of comparing them, from a layman's point of view, with Bellevue, the Massachusetts General, and other American institutions. The methods of instructing the students are of course practically the same in both countries. What most impressed me was the low grade of intelligence, the dense stupidity, in fact, of many of the young men to whose care the ills of humanity in these islands were about to be con-

fided. I have in mind particularly a class of young men about to pass their final examinations previous to beginning practice. I watched them undertake, one by one, to diagnose a long series of cases in the outpatient department of a great hospital. It is no self-conceit to say that with only a layman's knowledge I should have come nearer the mark in half the cases. Their book knowledge may be as complete as their diplomas will certify, but the practical application of it, the native intelligence which makes it valuable, was sadly deficient.—*London Correspondent of The Sun.*

A Pugilistic Physician.—Medicine with its many drawbacks is after all preferable to prizefighting, and we advise Dr. Payne, of Ohio, to stick to it; that is, if he is, as we have been informed, a real doctor of the practising kind. In an attempt to win pugilistic laurels from Boston's "Dick" O'Brien before the Eureka Athletic Club on April 6th, the latter gentleman is said to have promptly administered what he is pleased to call his Payne killer with such prompt effect that the physician did not require a second dose.

The Von Siebold Centenary in Japan.—On February 17th the one hundredth anniversary of the birth of P. F. v. Siebold was celebrated at Tokio. Addresses commemorative of his life and works, especially in Japan, were delivered by Messrs. Sugi, Miyake, Mutsumura, Fukuhi, Mitstkuri, Baelz, and Marumo. Von Siebold's first visit to Japan was in 1823, during the time of the feudal system, before foreigners were permitted any freedom in the country. Among other restrictions was one forbidding foreigners to have in their possession any map of the country, and one being found on him he was seized and imprisoned for six months. This reception did not discourage him, however, and he used his time of restraint to good advantage in study, and was able to continue his investigations, although under many restrictions for a while after his release. At his second visit he found the conditions very different, and took a large share in promoting the scientific growth of the country. He made many friends among the leading men of the empire, and to-day his name is honored among the Japanese perhaps even more than in his native land. Among the relics which the Japanese have piously preserved and which were exhibited on this occasion were a knife with which he had performed iridectomy and a plate which he had used in the examination of excreta. There were also shown portraits of himself, his daughter, and his two sons, and his works on zoology, botany, and the Japanese language.

Defective Sanitation in Italy.—According to Professor Bodio, of 8,254 communities in Italy, 1,454 have no supply of pure water, and 4,877 no regular sewage system.

An Unusual Termination to a Malpractice Suit.—Dr. W. O. Henry, of Omaha, has had a somewhat novel experience with the courts. He sued a patient for the amount of his bill and was in turn sued by the man for malpractice, damages being set at \$8,000. Not only was the doctor victorious in disproving malpractice, but he convinced the plaintiff and his attor-

ney of the justice of his cause, and the former went out and borrowed \$345 with which to pay what he owed for medical services, to save which he had instituted the malpractice suit.

The American Microscopical Society will hold its nineteenth annual meeting in the new Carnegie Library Building, Pittsburgh, Pa., Tuesday, Wednesday, Thursday, and Friday, August 18, 19, 20, and 21, 1896. An invitation is extended to all interested in the microscopical sciences. All communications relating to this meeting should be addressed to A. Clifford Mercer, M.D., president, Syracuse, N. Y., or to William C. Krauss, M.D., secretary, 382 Virginia Street, Buffalo, N. Y.

Mrs. Ludwig Wille died last month at Manitowoc, Wis., at the age of one hundred and five years. She was always in excellent health, and, as a correspondent informs us, was active and sprightly to the last. She attended to all her household duties the day before her death.

Illegal Practice of Medicine.—Several men have been arrested in this city during the past two weeks and sentenced to terms of imprisonment for practising medicine without a license.

The Women's Medical Institute in St. Petersburg has obtained ground near the Petropavlovski Hospital, and will begin the erection of its building as soon as the spring opens. It is expected to have the buildings completed in time formally to open the institute in August, 1897. It has been liberally subsidized by the government and by the municipality of St. Petersburg, and private subscriptions and donations have been neither few nor small. At present the capital amounts to about 600,000 roubles (\$300,000). But the greater part of this will be required for building and furnishing the institute. It has consequently been found impossible to provide residence for the students within its walls, as had been originally intended. Donations are, however, still coming in, and it is only a question of time for sufficient funds to be in hand to make up this deficiency. Already the institute has had one valuable legacy. The late Professor Tchudnofski left to the Women's Medical Institute his entire medical library, containing over four thousand volumes. The number of students who will be admitted to the courses at first has been fixed at one hundred and twenty-five. Over one hundred applications have already been received.

An Unclaimed Skull.—The dead-letter department of the national postal service contains among its curios a death's head addressed to the late Professor Gross. The sender evidently wished it to go as dead-head matter and neglected the postage, so it naturally found its way into this great postal morgue.

The Contagious Disease Law.—A warrant has been issued for the arrest of a Washington physician on the charge of violating the contagious disease law. It is alleged he failed to make a proper report of a case of diphtheria, and it is understood the case is brought to test the law.

Black Plague is said to have appeared in Yokohama. Three cases are reported by cable, in two of which the patients have died. They were both Chinese.

Capital Punishment in Ohio.—The Ohio State legislature has passed a bill providing for the execution of criminals by electricity instead of by hanging. The law will go into effect on July 1st.

Adder Bites.—A seventeen-year-old girl is critically ill at Fishkill-on-Hudson from nine bites upon the leg inflicted by a spotted adder.

Pharmaceutical Exposition.—An international exposition is announced to take place in Prague from August 15th to September 15th, at which, besides a section on pharmacy, there will be one on hygiene, including hospital service, mineral waters, bacteriology, and hydrotherapy.

Small-Pox in New Orleans.—The *Medical and Surgical Journal* of New Orleans says that small-pox has been prevalent in that city for the past two years, new cases occurring through the coming to the city of unprotected blacks from the country parishes. The board of health is hampered in its efforts to stamp out the disease by a lack of funds, and the journal calls upon the profession of the State to advocate general vaccination of unprotected persons, so that the supply, which now keeps up the disease in New Orleans may be cut off.

The Memphis Hospital Medical College graduated a class of sixty-seven on March 27th.

Barbers Object to the Dispensary Plan.—Cincinnati boasts of a tonsorial college where instruction is given in the arts of shaving and hair cutting. As clinical material was rather scarce the college recently advertised for subjects. The result was that hundreds of men went to the school for free shaves. This interfered seriously with the business of the barber shops, so the barbers' union petitioned the board of health to interfere, alleging that the school was not clean and that disease was likely to be spread by it. The health officer therefore visited the place and ordered that hereafter the school give its patrons clean towels, bay rum, and witchhazel. This so added to the popularity of the trichoclinic that the patients became too numerous for the students to handle, and the college has now adopted the New York Hospital plan of a nominal charge for professional attendance and hair-oil. A similar institution has been opened in New York, and we too shall have an object lesson in the benefits of dispensary treatment.

The Color Line in an Asylum.—The governor of Kentucky has appointed a colored man as assistant physician to one of the State hospitals for the insane, and an outcry has been raised against the appointment because some of the patients under his care are white.

Regulating the Sale of Patent Medicines.—There has been introduced into the Massachusetts legislature an "Act to Protect the Public Health by Regulating the Sale of Patent Medicines and to Determine the Amount of Alcohol or Liquor in Each Bottle," which provides that "any person or persons, firm,

or company offering for sale to the public any patent medicine of any kind whatsoever, shall present to the State assayer the formula or manner of making the same, and the State assayer shall certify upon every bottle or package that the medicine contained therein contains nothing injurious to the public health; and the State assayer shall also cause to be plainly marked upon the side of the bottle, in type not smaller than brevier, the amount of alcohol or liquor of any kind whatsoever contained in the bottle or package, and the person or persons, firm or company, shall make oath before a justice of a peace that the formula or manner of making the same is true, and shall deposit the aforesaid formula or manner of making the same, with sworn statement, with the State assayer." The penalty for each violation of the provisions of this act is a fine of not more than one hundred dollars.

Typhoid Fever caused thirty-six per cent. of the deaths among the British troops in India during the year 1894.

Diphtheria was the cause of over fourteen thousand deaths in Vienna during twenty-five years from 1870 to 1894 inclusive.

Contract Medical Services.—At the annual meeting of the Union County (N. J.) Medical Society, held April 8th in Elizabeth, Dr. George Westcott, of Fanwood, was elected *President* for the year. A long debate took place over the alleged violation by some of the members of a by-law which forbids them to make contracts with benevolent societies or families for medical service. This law was adopted three years ago. It was charged that some of the members had not only made contracts with societies, but with the families of the members of these societies, thus robbing the regular family physician of his practice. It was voted that the execution of the law be temporarily suspended and that the law be referred to the State Medical Association for its final decision.

Leprosy is said to be spreading in the Russian Baltic provinces with alarming virulence. Several hundred persons are said to be afflicted with the disease, and the Livonian Diet has just taken measures for isolating them at the cost of the State.

Treatment of Diphtheria in Berlin.—During 1894 and 1895, 245 diphtheria patients at Am Urban Hospital in Berlin were treated with antitoxin with a mortality of 28 per cent., while among the 146 who were treated otherwise the mortality was 42 per cent.: 53.2 of the serum cases were serious, 23.7 severe, and the rest slight. The effectiveness of the serum was proportionate to the earliness of its application and the strength of the first doses. The hospital reports conclude that antitoxin is not an infallible but a valuable remedy.

The California State Medical Society holds its annual meeting at Los Angeles on April 21st to 23d.

American Pediatric Society.—The eighth annual meeting of this society will be held at Montreal on May 25th, 26th, and 27th, under the presidency of Dr. Joseph O'Dwyer, of New York.

The National Confederation of State Examining and Licensing Boards will hold its fifth annual meeting in Atlanta on May 4th. The president of the confederation is Dr. William Warren Potter, New York; vice-president, Dr. James Mackintosh Hays, North Carolina; secretary and treasurer, Benjamin F. Griffith, Illinois.

A Good Reason.—The *University Medical Magazine* says that Dr. John B. Deaver has declined to accept the appointment as consulting surgeon to the Norristown (Pa.) Hospital for the Insane on the ground that services to State institutions should not be rendered gratuitously.

An Ingenious Fake.—One of the New York dailies, noted for the power of its imagination, recently printed an elaborate tale about a new international drink-cure sanatorium, the promoters being a syndicate of physicians from New York, London, Berlin, and Paris. The establishment is to be located, our contemporary says, on an island in the South Pacific where everything but alcohol may be had in abundance. The patients have to agree to stay on the island for a year, and in order to insure their keeping of their promise they will have to pay a year's board in advance. The place will be called "Medical Island" and will belong to Great Britain.

Clinical Sketches.—Mr. Noble Smith announces in *Clinical Sketches* of March, 1896, that the work of editing the journal interferes so greatly with his other occupations that he is obliged to discontinue his editorship. It is not determined whether another editor will take up the work or whether the publication of the journal will be abandoned. We hope the former will be the case.

Privileged Communications.—In Massachusetts, says the *Boston Medical and Surgical Journal*, the physician is not protected by the law in his refusal to betray a professional secret, but may be imprisoned if he refuses to do so when ordered by the court. The priest is likewise unprotected in his preservation of the secrecy of the confessional, but the lawyers have seen to it that protection is assured them in guarding the secrets of their clients.

Obituary.

JAMES WEST ROOSEVELT, M.D.,

NEW YORK.

DR. JAMES WEST ROOSEVELT died of pneumonia April 11th, aged thirty-eight years. From the time of the initiative chill the disease progressed so rapidly that he was ill but eighteen hours. His sudden demise has caused a painful surprise to a large circle of medical associates, and to a still wider circle in which he was an active and much-beloved personality. Of a genial disposition, frank manner, and earnestness of purpose, his influence for good was felt in all the directions of his varied and beneficent work. As a clinician and medical investigator he took a leading rank, his researches for the most part being confined to matters bearing more particularly upon respiratory diseases. An active member of many of the medical societies of the metropolis, he was a powerful and

ready speaker in all discussions and was a frequent and valued contributor to current medical literature.

He was a son of Silas Weir Roosevelt, at one time a prominent lawyer in this city, was born in this city on July 2, 1858, and was graduated in 1880 from the College of Physicians and Surgeons. He was a member of the Academy of Medicine, the Medical and Surgical Society, the Practitioners' Society, and the Pathological Society of this city. He was particularly active as the representative of the Academy of Medicine in its efforts to abolish the pollution of the Croton water-shed and in its efforts to secure a national control of quarantine matters. He was also well known as a contributor to the magazines. He was visiting physician at the Bellevue, Roosevelt, and Seton hospitals. His widow survives him, with three children.

JAMES JAY MAPES, M.D.,

NEW YORK.

DR. JAMES JAY MAPES, one of the best-known among the younger physicians of this city, died April 14th at Saranac Lake after an illness of ten months. Dr. Mapes, who was a son of Charles V. Mapes, was twenty-nine years old, and was graduated from the School of Arts of Columbia College eight years ago. He was well known as an athlete during his college course, and his popularity among his associates was so great that for three years he held the presidency of his class. He commenced the study of medicine at the College of Physicians and Surgeons in this city, and at his graduation stood first in his class. During his course there he studied in the summers at the University of Edinburgh, where he won the gold medal given for the highest honors in anatomy, a distinction which had never previously been gained by an American. After an internship in the New York Hospital he spent a year in Vienna and Paris, and in the latter city attracted the attention of Dr. Roux, with whom he studied the antitoxin treatment for diphtheria. On his return to New York last year Dr. Mapes was made the physician in charge of the Nursery and Child's Hospital, and he remained in that post until the disease which caused his death suddenly developed. Two years ago Dr. Mapes was taken ill with pneumonia in Paris, since which time pulmonary phthisis developed, which finally terminated his life.

IRVING WHITALL LYON, M.D.,

HARTFORD, CONN.

DR. IRVING WHITALL LYON died of pneumonia at his home in Hartford, Conn., March 4th, in the fifty-sixth year of his age. He received the degree of M.D. from the University of Vermont in 1862, and from Columbia, N. Y., in 1863; was demonstrator of anatomy, Berkshire Medical College, Pittsfield, Mass., in 1862, acting assistant surgeon U. S. Army in 1862, served on the staff of Bellevue Hospital, New York, 1863-64, since when he had practised his profession in Hartford, Conn. He was the president of the Hartford County Medical Society at the time of his death. He had been the medical director of the Hartford Life and Annuity Insurance Company since 1866. He was the author of various articles in the Transactions of the Connecticut State Medical Society, the journals of New York, Philadelphia, and elsewhere, and in 1891 published a volume entitled the "Colonial Furniture of New England," a critical historical study of the domestic furniture in use in the seventeenth and eighteenth centuries, which has since been regarded as a standard authority in this country and abroad. At the time of his death he had in preparation an exhaustive critical study of the "Colonial Architecture of New England," which he had expected to publish by next winter.

Clinical Department.

A CASE OF ACUTE YELLOW ATROPHY OF THE LIVER.

By SHERMAN VOORHESS, M.D.,

DAGGETT, PA.

MARCH 31, 1895, I was called to see B. J.—, aged thirty-two, male; occupation, farmer; a widower of nine years. Complexion sandy, figure erect, of healthy appearance, body muscular and well developed.

I found him complaining of pain in the epigastrium, some vomiting, aching limbs, chilly sensations along the spine, and severe headache. His temperature was 99° F.; pulse, 80; the tongue was covered with a thin white coating and the appetite was lost. I thought from the appearance of the case that probably influenza with gastro-enteric disturbance was the trouble, and I prescribed accordingly. Two days later I was summoned and found the temperature 100° F., pulse 90, respiration normal, tongue coated. The patient was vomiting frequently; the epigastrium was tender; there was some tympanites; the liver dulness was about normal; the limbs ached—he was "aching all over," as he expressed it. The bowels were constipated, but yielded to cathartics. The case ran along for a week with but very little change in any of the symptoms. At the end of the week the liver area began to grow tender and there was considerable tenderness with tympanites over the abdomen; the area of hepatic dulness seemed somewhat increased, so that I suspected malaria, although the more characteristic symptoms of malaria were absent.

At times there was slight delirium at night. The temperature did not go above 100° F. nor the pulse above 90 per minute; the tongue remained coated and vomiting was a troublesome symptom.

I might add here that just previous to this case I had a number of patients with similar symptoms, who after being ill for a few days developed a catarrhal jaundice lasting usually for a week. Therefore I was not surprised to find in this case ten days from my first visit some jaundice, which gradually spread until by the morning of the twelfth day the whole body was jaundiced, the upper portion being deeply injected. The pulse remained at 90 and the temperature at from 99° to 100° F. There was now obstinate constipation and what was passed by the bowel was clay colored. But little urine was voided and that little was deeply stained.

On the night of the twelfth day I was called hastily and found the patient delirious and violent, requiring several attendants to keep him on the bed; he was noisy and cried loudly. The jaundice was deepening rapidly. A hypodermic injection of morphine soon quieted the patient, and by repeated doses I was able to keep him quiet. The following morning the patient was resting easily, but there was low muttering delirium. The discoloration if possible was more pronounced than in the night previous; even the bed linen was deeply stained. The liver dulness seemed diminished; still I would not be positive of this, as a distended colon might have caused error. I asked the night previous for a sample of the urine, but found it had been carelessly thrown away, so that no test for leucin or tyrosin was made. The urine was passed at this time involuntarily and but little at a time.

Hiccough lasting several hours came on and seemed to cause much pain at each spasm. The respirations were fast becoming labored, the pulse was intermittent and 130 per minute. The patient evinced no sign of pain on percussion over the liver or abdomen. This was probably due to the opiate. At 10 P.M. Dr. J. H. Nye was called to see the case and agreed with me

that it was one of acute atrophy of the liver. At this hour the pulse was 160, temperature 99° F., respiration much accelerated. The pupils were unequal in size and the patient was unconscious; both right extremities seemed paralyzed and everything pointed to a cerebral hemorrhage having occurred. Death soon closed the scene.

By the greatest effort we were allowed only a very limited autopsy. An incision was made over the liver, the skin and the fat underneath it being intensely yellow. Upon opening the abdominal cavity, it was found to contain much dark icteric fluid and the viscera were all discolored. The liver was sought out and examined. The capsule was loose; the organ seemed about one-half its natural size. The lobes were flattened and turned upon themselves on being handled, seeming to have lost their original texture. The organ was so soft that I could easily put my finger into its substance. On section it was seen to be of a dark yellow color and could be cut easily, like a liver that had undergone post-mortem changes. The lobulated appearance of the normal liver was entirely absent. The gall bladder was distended. The abdominal cavity presented evidence of ascites, the fluid filling the whole cavity.

The spleen was much enlarged, of a yellow mottled appearance, the right extremity of this organ overlapping the left lobe of the liver by about two inches. On section it was seen to be of a dark yellow hue.

The kidneys were not examined.

Now, while no test was made for leucin and tyrosin, still I think evidence enough has been presented to warrant my diagnosis of acute yellow atrophy.

We find in most text-books that venereal disease is a predisposing cause of this trouble. This man gave a history of two severe attacks of gonorrhœa, each lasting many months; at one time he had a urethral fistula. Some weeks before his illness I examined him and found a stricture extending nearly the whole length of the prostatic portion of the urethra. This was operated upon with success.

The case seemed to me of uncommon interest from the past history of venereal disease and from the fact that the disease appeared to be engrafted upon a simple form of gastro-enteritis, in which we often see the process extend to the gall ducts and cause catarrhal jaundice.

MYXOFIBROMA OF THE BLADDER IN A CHILD THREE YEARS OLD.

By GEORGE K. SIMS, M.D.,

IN CHARGE OF THE SURGICAL AND GENITO-URINARY DEPARTMENTS OF THE FREE DISPENSARY, UNIVERSITY COLLEGE OF MEDICINE, RICHMOND, VA.

ON December 28, 1895, Rosa S.—, aged three years, female, colored, was sent into my department. She was very much emaciated and her appearance gave evidence of great suffering and severe illness. She had not passed her urine for three days, except a little that dribbled out. From her mother I obtained the following history: For the preceding eighteen months the child had had difficulty in evacuating the bladder and bowels, and had suffered a great deal with a straining, as she thought, to empty the bowels. These symptoms had gradually grown worse until three months previously a large tumor had developed in the lower part of the abdomen. She had a prolapse of the rectum and there was a mass about the size of one's finger in the vulva. Three physicians who had treated her previously said that this was the womb which had come down, but they had failed to get it back into position after several attempts. Upon a hurried examination I made the diagnosis of a tumor obstructing the urethra and that the abdominal tumor was the bladder

enormously distended with urine. After some difficulty I succeeded in introducing a small silver catheter and drew off about half a pint of very offensive, ammoniacal urine. This removed the abdominal tumor and confirmed my diagnosis.

The vulva was so completely blocked up by the mass that it was very difficult to find its attachment, but a closer examination showed that it was attached about the vesical neck. Owing to the extremely debilitated condition of the child, and the inflamed condition of the urethra and bladder, it was not considered advisable to undertake the operation of removing it at that time. She was given salol and boric acid to render the urine aseptic, and appropriate treatment to improve her general condition.

After about ten days of this treatment and before the day set for the operation, the tumor slipped back into the bladder; several days later a large portion of it sloughed off and passed out, so that she could pass her urine without the use of a catheter, which she had not been able to do before. In the mean time her condition had improved so much that her mother would not consent to an operation. A portion of the tumor was left and it was evidently growing very fast, for it was not long before it began to obstruct the urethra again, and when she bore down it could be seen trying to engage in the urethra.

On the morning of February 28, 1896, I was notified that it had come out again, so I decided to operate at once. After a hurried preparation chloroform was given, the urethra was dilated, and by digital examination the tumor was found attached to the anterior wall of the bladder just above the urethral orifice. With a finger it was pulled out as far as possible and enucleated with curved scissors, this being the only means of getting at it, as owing to the large size of the pedicle and to its close attachment to the bladder walls, the snare or thermo-cautery could not be used. She rallied very well from the operation and is getting along as favorably as could be expected. In addition to the medical treatment her bladder is being washed out twice daily with boric-acid solution.

The whole mass weighed about three ounces. Microscopical examination showed it to be a myxofibroma, a very rare neoplasm for this location, and its size was remarkable for a child of this age. Another peculiar feature is that it was attached to the anterior wall of the bladder and not to the base, the usual situation.

621 EAST FRANKLIN STREET.

PERSONAL EXPERIENCE IN THE ANTITOXIN TREATMENT OF DIPHTHERIA.

By B. SCHEINKMAN, M.D.,

NEW YORK.

FROM my personal experience with antitoxin in more than thirty cases I can with difficulty restrain myself from becoming too enthusiastic concerning the value of this mode of treatment. The results obtained by me with this new remedy, as compared with our old method of treatment in apparently identical cases, are very striking indeed. Leaving out all the milder and questionable cases and considering only the most typical and severe forms of the disease, especially those complicated by laryngeal croup in which intubation was absolutely necessary, I do not believe that I ever succeeded in saving more than twenty per cent. by the most approved of the old methods, while, since resorting to the antitoxin treatment, I can positively assert that over ninety per cent. of the most severe and apparently hopeless cases of laryngo-pharyngeal diphtheria were actually saved.

I may say that the number of my cases is too small to draw any positive or valuable conclusions, yet

I regard them as worthy of record. In all cases the diagnosis was confirmed by the bacteriological bureau of the Board of Health.

CASE I.—Rosa R—, three years of age; posterior pharyngeal wall and both tonsils covered with pseudo-membrane; temperature, 103° F.; laryngeal stenosis not severe; she was treated with bichloride and iron in appropriate doses. Forty-eight hours after the onset I was called in the night and found the child cyanotic from severe laryngeal stenosis; temperature, 104° F.; pulse very rapid and irregular. The child was very restless and suffocation seemed impending. I immediately intubated and six hours later injected 20 c.c. of antitoxin, all other medication being discontinued, with the exception of some brandy and steam inhalations. Twenty hours later I found the child's respiration perfect; the color of the pseudo-membrane was considerably changed and it was partly detached; temperature, 101° F.; pulse better. The child looked more cheerful and wanted to eat. As she was steadily improving the tube was removed on the sixth day, and at the end of the eighth day complete recovery was established. At the time of administering the antitoxin to Rosa, I insisted upon inoculating all other children of the family with small doses of the remedy for prophylactic purposes, but succeeded in doing so with only two of them; one child, fearing the needle, managed to escape and was left unprotected. Three days later the unprotected one (who was about seven years of age) developed a very severe form of diphtheria and was at once subjected to antitoxin treatment and fortunately has also recovered. Those children who were prophylactically treated, notwithstanding their constant mingling with the sick ones, and although younger than the unprotected one, escaped infection. This case tends to show the efficacy of the remedy not only in the active and well-developed state of the disease, but also its prophylactic properties.

CASE II.—Joseph W—, age two and one-half years; naso-laryngo-pharyngeal diphtheria; submaxillary glands enormously swollen; dyspnoea not severe enough to require intubation; temperature, 105° F.; pulse, 150. Was treated for two days with bichloride and iron. As the symptoms were not abating I administered 18 c.c. of antitoxin. The next day the membrane had changed in color; temperature three degrees lower; pulse, 110; dyspnoea greatly relieved. I stopped all other medication except brandy and steam. The child continued improving every day, and on the sixth day was discharged as cured.

CASE III.—Lasar L—, age seven months; both tonsils and pharynx covered with a grayish-colored false membrane; both submaxillary glands very much enlarged, severe dyspnoea with a characteristic croupous cough; temperature, 104° F.; pulse, 160; general condition of child precarious. I immediately injected 8 c.c. of antitoxin, excluding all other medication except brandy and steam. The next day there was no change in the general condition of the child. I injected another dose of 15 c.c., and on the following day I found a change in the appearance of the membrane; pulse, 120; temperature, 104° F.; dyspnoea slightly diminished. The general condition of the child was improved and he was discharged as cured at the end of fourteen days.

CASE IV.—Elias S—, age two years; laryngo-pharyngeal diphtheria; severe dyspnoea with cyanosis; temperature, 105° F.; pulse uncountable; great restlessness and impending suffocation. I immediately intubated and injected 18 c.c. of antitoxin, excluding all other remedies. Fifteen hours later I found the child's respiration almost free, pulse much improved, temperature the same. The child continued to improve every day, until on the seventh day I removed the tube,

although the temperature had not yet reached the normal. Six or seven days after my last visit I was called again to see the child. On inquiry I was told that the patient had been getting along very well until that morning. On examining the child I found nothing to account for the high fever, which I found to be 105° F., except a slight bronchial catarrh and a mild form of pertussis, from which the patient had been suffering for a couple of months previous to its present illness. I administered an antipyretic without the slightest effect. The child grew worse every day, until finally, after four weeks of this continued unaccountable fever, the patient died with symptoms very much resembling those of tuberculous meningitis. Even this case I consider as successful so far as the diphtheria is concerned, for my impression is that the child died of an incidental tuberculous meningitis, but at the same time I must confess that possibly what appeared to me as a tuberculous meningitis might have been the much-spoken of poisonous effect of the antitoxin.

CASE V.—X. Y.—, age two years. I was called up at 4 A.M. in a hurry and found the patient in a most precarious condition. The throat was covered by diphtheritic membrane; the submaxillary glands were enormously congested; temperature, 104° F.; pulse could not be counted; the cyanosis was extreme; the patient was semicomatose with cold extremities, and seemed to be *in extremis*. I immediately intubated and ordered frequent administration of brandy while waiting for a dose of antitoxin, which was administered three hours later. But, owing to the extreme severity of this case on the one hand and to the uncertainty and shaky confidence in the new remedy on the other, I did not dare to withhold the old routine treatment entirely and ordered that the bichloride and iron, in conjunction with stimulation, be continued. The next day I found little improvement and almost lost hope for the patient. I decided, however, to try another dose of antitoxin (15 c.c.), keeping up stimulation but excluding other remedies. The following day on entering the sick-room I was astonished to find the child sitting up and fighting with its mother against the administration of some brandy. On examination I found the greater part of the membrane had disappeared; the pulse was 120; temperature, 101° F.; the glandular engorgement was considerably diminished and the general condition of the child was very good. The child made an uninterrupted recovery.

All my other cases, of about the same gravity and numbering twenty-seven, recovered, except two. These proved fatal, notwithstanding the antitoxin, which had been resorted to late in the disease. It is also important to bear in mind the fact that these five cases are examples of a series of only the most severe forms of the disease, while in milder cases I seldom, if ever, resort to antitoxin, but treat them according to our old methods. In fact, since the introduction of the antitoxin in my practice, a fatal case of diphtheria is a phenomenon with me, provided the disease is seen in an early stage.

THE FLOATING OR MOVABLE KIDNEY.

By CHEVES BEVILL, M.D.,

WINFIELD, ARK.

IN 1888 I reported in the *Medical Bulletin* three cases of floating kidney. They were all in women. Since then I have seen three other cases—two in women and one in man. They are as follows:

CASE I.—Woman, aged thirty-three, married; mother of two children. When in the eighth month of pregnancy with the second child, she began to complain of a strange feeling in her right side. I advised absolute rest and administered anodynes to give ease. After ten days' rest (during this time while in bed

she was comparatively easy) she got up and in two or three days was taken with the same strong bearing-down sensation in her side. The pains in her side grew worse. Labor came on, lasting four days. The fetus was born dead, as the waters had been escaping for three days prior to its birth. The woman did well while in bed and until she resumed her housework, when the same feeling of distress came on worse than ever. I had not seen her for over one month. I was then called to see her for a tumor in her right side, which greatly distressed her. I found it to be the right kidney. As she was a very lean, slim woman, there was no difficulty in recognizing the trouble. An abdominal supporter with a pad was used and all was righted. Since then she has had several times a return of the trouble, but an adjustment of the bandage with the use of galvanism has relieved her.

CASE II.—Married lady, aged thirty-six, mother of two children, both living and healthy. Was seized with great pain in her right side after a walk of one and one-half miles. When called to see her I found that she had been suffering for six hours with a keen cutting pain in the right iliac region or just above. She was vomiting every few minutes and passing water at frequent intervals. Pulse quick and hard, 120; temperature, 103° F.; respiration, 32. There was such a degree of tenderness in her side that it was out of the question to make any pressure whatever. She would lie on her back with her limbs flexed when not vomiting, and I thought she had appendicitis. I finally quieted her by hypodermic medication and hot applications to the painful point. I thought that I would await further developments and if necessary get help and operate, as I had lost one patient two years before from appendicitis (a man who would not agree to be operated upon). Eight hours later, when the patient was easy and could talk, I obtained information that made all clear to me. She had carried one of her children, eight months old, on her left arm and the other, two years old, a very fleshy one, astride of her right hip for over half a mile. The tenderness gradually subsided, so that I could outline the displaced kidney. This I replaced and put on a bandage. In three days she was up but had to wear the bandage for several months. She has done very well since.

CASE III.—Man, a farmer, aged twenty-five, well built. On December 6, 1895, I was sent for by his physician to go and operate on him. The patient was thirty-three miles away. I went prepared to open the abdomen, but when I arrived I found that it was now the eighth day of the trouble. The patient spoke to me, but appeared to be somewhat in distress. There was no fever; pulse, 82; respiration, 19, when quiet. Lying on his back with his legs drawn up, he could not put his right leg out straight. A tumor was plainly to be felt in the region above the appendix. There were pains darting down the right spermatic cord; the testicle was retracted. He had vomited for three days and nights and was troubled with frequent urination.

The history of the case was that he was stricken after helping put some cotton bales on a wagon. He sent for a physician, who diagnosed appendicitis and treated him on general principles for such. I could make nothing out of the case but a displaced kidney, and we waited until the next morning (as I saw no immediate danger). I could press the tumor back to the place where the kidney belonged. The patient became easier, although pressing on the tumor made him sick. This confirmed my diagnosis to my mind. Next morning the patient was easy and I left for home. I saw him January 23d, twenty-seven miles from his home. He cannot stand erect without pain and has not been able to do any work, but has worn no supporter.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL ADVERTISING—PATHOLOGICAL SOCIETY OF LONDON—MULTIPLE EXOGENOUS ADENOMATA OF THE THYROID—ACTION FOR SLANDER AGAINST DR. PLAYFAIR—VERDICT OF £12,000 DAMAGES—NEWPORT HOSPITAL—THE LATE DR. BRAEAZON.

LONDON, March 27, 1896.

ADVERTISING is just now the "burning question" in medical circles. Perhaps I should rather say it is the subject which touches on and threatens to absorb most others. What is advertising? What form of advertising is legitimate? What constitutes unprofessional advertising? Such and such like questions abound in medical gossip and occupy medical casuists. The treatment of such points in the so-called ethical column of the *British Medical Journal* has unquestionably increased the irritation of jealous and envious men by furnishing them a platform from which to proclaim or insinuate that their rivals availed themselves of unprofessional ways of obtaining practice. It is curious that some people cannot see that unprofessional is only another word for ungentlemanly, and that in a body of more than thirty thousand men it is not surprising that now and again one meets with a person whose claim to the name gentleman cannot be made out. It is more curious still, quite funny, to see queries submitted and solemnly adjudicated, as to how a doctor may have his visiting-card printed or what sort of a door plate he may have, or whether a duplicate of the latter may be fixed to the side of a corner house! Closely allied to the last query was the verdict which mulcted the editor of the journal in damages for libel. He had pronounced against a doctor whose plate had been affixed to a hydropathic establishment of which he was the visiting but non-resident adviser. To the surprise of most people the doctor promptly sued the editor for libel, and to the astonishment of every one was successful. But out of this trial still more curious developments have cropped up. Thus, Mr. Lawson Tait writes to the *Medical Press* to say that while the action was being tried he read in the court circular of the *Times*: "Mr. Ernest Hart has left for a yachting tour on the Riviera for the restoration of his health, which has not yet recovered from the overstrain of his recent sanitary tour in India." Mr. Tait's curiosity induced him to apply to the publisher of the *Times*, who sent him a printed reply that "such insertions are charged for at the rate of three lines for a guinea and 10 shillings and 6 pence for every additional line." Thereupon Mr. Tait wants to know "what is guilt and what is innocence in advertising?" If Mr. Hart thinks it worth his while to spend his superfluous guineas in advertising his movements, he will do so without consulting Mr. Tait as to whether it is professional or gentlemanly. But it seems scarcely consistent for the ethical column to denounce in others the very act of the editor. Howbeit, I hope the editor pays for the privilege of airing his own taste in advertisement, and that the amount is not debited to the journal. Another correspondent on these ethical points wants to know who sanctioned the payment of £100 to Sir Dyce Duckworth for his evidence at the trial, evidence which in fact gave away the case. And further, this inquisitive correspondent asks who invited Dr. Cousins, who is chairman of the council and on the editorial reference committee, to be a witness? Because of this, he says, Dr. Cousins should have made no claim for his services, to which it might be replied his offices are honorary. If he

were a paid servant of the association it would be different.

Sir D. Duckworth can scarcely feel gratified at the notoriety he has attained in this matter. It was disagreeable enough at the trial for counsel to press him respecting the leaflets of his insurance company. "*Et tu, Brute!*" is not a pleasant argument. But this phase of his doings is eclipsed by the publication in the *Rochester Diocesan Chronicle*, a monthly periodical, of the paper on "Clerical Breakdown," read at the house of the rural dean by Sir D. Duckworth, physician, etc., and lay reader in the diocese of Rochester. People are declaring that if the treasurer of the Royal College of Physicians may thus disport himself in a sort of parish magazine, Messrs. Jones, Brown, and Robinson ought not to be blamed because the editor of the *Little Peddington Gazette*, when the gasworks blew up, reported that these three respected fellow-townsmen were soon on the spot and did all that medical science could do to alleviate the sufferings of the injured. "What is sauce for the goose is sauce for the gander." If I have dwelt too much on advertising, it is because it furnishes a key to several other questions about the unwritten "ethical code" for the floodgates have been opened and we are overwhelmed with streams of discontent and envy.

At the last meeting of the Pathological Society, among other specimens was one of multiple exogenous adenomata of the thyroid gland from the right side of the neck of a man of twenty-two. It was of a very unusual character, for the mass was a conglomeration of a large number of distinct growths loosely held together by connective tissue. Structurally they presented in part the character of normal thyroid tissue, but in part the gland spaces were distended with multiform epithelial cells and the colloid occurred as collections of discrete droplets lying amid the cell masses. Mr. Shattock discussed the possibility of the tumor being akin in its origin to the compound kidney of the bear, seal, cetacea, etc., but he had been unable to find that such a disposition of the thyroid ever obtained in any vertebrate forms. The explanation he held to be that the multiplicity arose from an exogenous formation of adenomata. It was not rare to find adenomata embedded in goitres (endogenous), and in the present specimen sections disclosed all stages between the formation of adenomata at the surface of certain of the growths and their complete isolation, the whole process being parallel with that seen in subperitoneal myomata of the uterus.

Mr. James Berry brought fifteen specimens of thyroid cysts and adenomata from museums to show the manner in which certain common and important thyroid cysts were formed, namely, from solid adenomatous nodules by the gradual breaking down and liquefaction from the centre of these several nodules. Many so-called cysts removed by enucleation could be shown, if properly prepared by hardening in spirit, to be really adenomata. These specimens showed all degrees of transition between the early solid adenoma without any cyst to the almost completely cystic tumor in which mere traces of gland tissue adhering to the inner surface of the cyst wall were all that remained of the original solid adenoma. Cysts formed in this way are particularly well suited for enucleation, since the cyst wall is usually thick and only loosely embedded in the surrounding thyroid-gland tissue. In contradistinction to these cysts two other specimens were shown of thin-walled smooth cysts with clear straw-colored contents. These, it was considered, did not belong to the same class and had never contained adenomatous tissue within them. Mr. Berry asked Mr. Shattock how far his specimen was artificial—that is, how far the thyroid capsule and accompanying connective tissue had been dissected away from the growths

It should be remembered that when adenomata grew toward the edge of the gland the proper thyroid tissue surrounding them gradually became thinner. Mr. Golding-Bird asked, with regard to two of the cysts Mr. Berry had shown, what was his ground for regarding them as anomalous. Mr. Shattock said that there was practically no dissection of the specimen. Even the small growths lay quite at the surface of the parent mass. Mr. Berry said he regarded the cysts as anomalous because, the lining of the cysts being smooth, it was in that respect quite unlike the other class of thyroid cysts.

A verdict for £12,000 damages was given to-day against Dr. W. S. Playfair for slander in communicating to a third party an opinion he had formed in his professional capacity involving the honor of a lady. The defence set up was privilege and the duty of protecting his own wife, who is the sister of the lady's husband. Dr. Playfair said he removed from the patient a piece of recent placenta, and her husband was not in England at the time such could have been formed. Other evidence was given to the effect that what he removed was a blighted ovum. The question of professional confidence in its various bearings came before the court, but as the trial is only just over and there may be an appeal, there is only time by this mail to report the verdict, which elicited tumultuous applause that was suppressed only with difficulty.

Professor Fraser, of Edinburgh, came to London last week and lectured on Friday at the Royal Institution on "Immunization against Serpent's Venom and the Treatment of Snake-Bite by Antivenene," as he calls it. Can we not find something better in English? Anti this, anti that, and anti the other are most distracting. Dr. Fraser exhibited specimens of the dried venom of different serpents.

The London County Council has elected Dr. W. J. Collins vice-chairman.

Dr. and Mrs. Garrod Thomas, of Newport, Mon., offered £5,000 toward the erection of a new infirmary if the additional sum of £15,000 required for the purpose can be raised.

Dr. Brabazon, who died on the 13th, practised at Bath for thirty-five years, and during the most of this period he was physician to the Mineral Water Hospital. He was also for a time medical officer of health, and was highly esteemed by his brethren. The last number of the *British Medical Journal* contains an interesting account of his views on rheumatoid arthritis written some months ago. His position at the Mineral Water Hospital gave him a large experience with that disabling and painful disease.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE CONGRESS OF BALNEOLOGY—A NEW METHOD OF TREATING WOUNDS—PALPATION BY A SOUND IN THE STOMACH—SCARLATINA ANTITOXIN.

ACCORDING to their yearly custom on the approach of spring, the German balneologists have met and discussed subjects of particular interest to them in their chosen specialty as well as others belonging more to the domain of general medicine. After a day spent by the members in visiting various institutions, the congress was opened in the evening at a session of the Hufeland Society. Prof. Oscar Liebreich was the president of both this society and of the congress. Among other things of interest the members inspected Lassar's dermatological collection and also were present at a demonstration by Litten of an arterial phenomenon, in which by slight pressure on the arterial wall he was able to produce a murmur.

At the opening session Dr. Schleich demonstrated

his new method of treating wounds, which seems destined to mark an epoch in our surgical therapeutics. He first, in the presence of the assembled physicians, removed a piece of the diseased clavicle from a woman, the operation being done under cocaine anaesthesia. Then he applied his new formalin-gelatin dressing. This renders all other forms of antiseptic wound treatment superfluous. By means of the vital activity of the cells formalin is gradually drawn away from its combination in this dressing, and acts in a nascent state with great antiseptic power. Suppurating surfaces are speedily converted into simple uncomplicated wounds, and furuncles, felons, and the like are healed in an astonishingly brief period. Dr. Schleich exhibited a large number of patients whom he had so treated, and his paper received the greatest commendation from all. It remains to be seen how this method will be received by our leading surgeons—better, it is to be hoped, than the same Schleich's method of cocaine anaesthesia, which has never received the approbation which it deserves.

Dr. Boas followed with the description of a new method for mapping out the lower limits of the stomach. He showed that the ordinary flexible sound, when the stomach was empty, applied itself exactly to the greater curvature, and in the majority of cases could be felt here on abdominal palpation and could be followed along its whole length to the pylorus. All other methods of determining the lower border of the stomach give uncertain or fallacious results, while by this sound palpation all danger of error is avoided. This same method is applicable to the determination of the position of the transverse colon, but not yet so perfectly that it can be relied upon for purposes of diagnosis.

In the general session, at which there were many of the four hundred and twenty members of the Balneological Society present, Landolt read a very interesting paper on the new elements argon and helium, two constituents of the atmosphere which are, however, by reason of their chemical inactivity and because of their non-existence in animal or vegetable organisms, of no significance in practical medicine. Schuster, of Aachen, then spoke of the results of the treatment of chronic myelitis with hot baths. Markus, of Pymont, read a paper upon the relation of attacks of migraine to meteorological conditions, a subject with which he had had painful personal experience. He believed that the attacks of migraine were called forth by changes in the electrical tension in the atmosphere. Karfunkel, of Cudowa, presented a communication which aroused much interest, upon the electrical conductivity of twenty-six natural waters which he had tested. He stated that every spring was characterized by a special conductivity which was greater in proportion to the amount of salts contained, and was less in waters containing a large amount of carbonic acid gas. This was followed by a paper by Schulz, of Greifswald, on the therapeutic value of sulphur and of sulphur baths, which he had come to regard, as a result of experiments upon himself and his students, as very high.

The "Curative Serum of the Hydropaths" was the title of a paper by Professor Winternitz, of Vienna, in which he discoursed upon the beneficent action of water in the treatment of infectious diseases. The natural internal curative force, strengthened by means of a rational employment of water, was what he denominated the "Autoheilserum" of the organism, through which the latter is assisted in its resistance to disease processes. He attributed to the body, stimulated by the action of the cold or the heat of the water, the capability of forming from its own constituents, so to speak, an antitoxin. In support of this view the speaker said that the same phenomena,

namely, leucocytosis and increased alkalinity of the blood, were produced by a rational "water cure," as by specific therapy. These views received further support in a paper by Strasser on the chemical changes in the blood and urine induced by the action of heat and cold. Klemperer presented a communication on the employment of hydrotherapy in Leyden's clinic. The paper, which was somewhat concise and aphoristic in form, called forth a lively expression of dissent from many speakers. The reader of the paper believed that the chief value of water was in its action upon the nervous system, and that this was mainly in the way of suggestion, that is, by quieting the patients; it was, however, often of excellent service in purely nervous affections. He dwelt upon its mode of application in nervous disturbances, asthma, heart diseases, and catarrh of the stomach.

Another interesting subject discussed was the treatment of pulmonary phthisis. After Winternitz had advanced the claim that he had cured thirty-two per cent. of his cases by hydrotherapy—a favorable result which he attributed to the strengthening of the resisting powers of the organism by water—and others had reported good results from mud-baths and tuberculin injections, Hansemann insisted that a spontaneous cure of tuberculosis was of much more frequent occurrence than we had unfortunately come to assume in this tuberculin period.

The sittings of the congress came to an end after four days, the closing function being a banquet at which many of the ladies of the members assisted.

Dr. A. Baginsky has made a report upon fifty-seven cases of scarlatina treated at the Kaiser Friedrich Hospital by the Marmorek antistreptococcus serum. This serum, a supply of which had been sent to the speaker from Paris by its inventor, acts only against the complications of scarlet fever which are due to the presence of the streptococcus. According to Marmorek, who has treated one hundred and three cases with the serum in doses of from ten to eighty grams, the remedy not only cures the complications but prevents their occurrence. The results of Baginsky's experiments with the serum were as a rule favorable. With the exception of a few cases in which the remedy had absolutely no effect, for example, that of a child with glandular suppuration in whom sixty cubic centimetres had been injected, most of the patients recovered without any complications. The number of cases is yet too small to allow of a definite opinion concerning the value of the antitoxin, but the remedy was employed sufficiently often to show that it is without injurious effects, since no untoward symptoms, such as collapse and the like, were observed.

OUR PARIS LETTER.

(From our Special Correspondent.)

ARTIFICIAL MILKS, USE OF DELETERIOUS—GROCERS AND THE SALE OF MEDICINES—THE LEAGUES OF PARIS—APPROPRIATION FOR LABORATORIES—HEALTH OF THE CITY—THE CHAMBER OF DEPUTIES AND THE DOCTORS.

PARIS, April 1, 1896.

Artificial Milks.—Sterilized milk, maternized milk, Pasteurized milk, and phosphatized milk, are pompous and high-sounding names with which dealers in the lacteal fluid stamp their wares which are recommended as substitutes for natural human milk. Injustice and often injury is done, not only to the child who is nourished by them and who certainly has a right to its mother's milk, but also to the mother herself, who is only truly such when she carries and nurses her child. These are laws of nature that it would be well to promulgate afresh and emphatically, because they

are beginning to be forgotten since numberless interested advertisements, unfortunately often coupled with medical endorsements, are constantly appearing in print, vaunting the merits and advocating the superiority to mothers' milk of sterilized milks, maternized milks, phosphatized milks, naturally or artificially prepared. The public, led into error by reading these artfully prepared notices in the daily press or lay-medical and health journals, end by believing that mothers' milk can be thus easily replaced and without serious objection.

This substitution is nevertheless highly deleterious, and it is a crying injustice to deprive children of their mothers' milk under the fallacious pretext of substituting therefor Pasteurized milk. Pasteurized milk, that is to say, cows' milk passed twice to a temperature of more than 60° C., evidently no longer possesses, after the coagulation of the albumin and a part of the casein, the properties of a good, digestible, and sound milk. It is well known that children brought up on such milk are more delicate and less well-developed than those nursed by their mothers. It is true that some succeed in overcoming this scanty nourishment and thrive in spite of the insufficiency of nutritives when they are of an unusually good constitution and come of remarkably strong and healthy parentage; but many fade and those that do not die grow up delicate or sickly when they might have been vigorous and well developed with their mothers' milk. The robust and buxom peasants too frequently leave the fields to come to Paris and nourish the children of the rich. They are to be had so readily from the Bureau des Nourrices that the Parisian ladies of wealth and fashion rarely accept maternity in its full signification; they accept of it only what they cannot refuse; that is, they give to the child about half what they owe it. If they could have the child carried in the fullest sense of the term by the mercenary woman, most of them would not hesitate a moment to do so.

Maternized milk, a happy name with which to baptize a new production, is simply cows' milk which is modified by the action of cane sugar upon the casein contained therein and thus made to resemble more or less mothers' milk.

Another method of maternizing milk is to add to cows' milk a certain quantity of artificial serum composed chiefly of salt and water. Phosphatized milk is obtained by the addition of the phosphate of soda to cows' milk in the proportion of from fifteen to thirty grains to the litre. Sterilized milk obtained by heat is but another name for Pasteurized milk, of which we spoke above. All these are pretexts for foreign nourishment and it is the duty of every physician to oppose vigorously the generalization of such deleterious substitutions; the more so at the present time, as the warm months are at hand, and the first and second summers of infancy are the ones in which there is the greatest mortality from infantile diarrhœa, cholera infantum, and athrepsia.

Grocers and the Sale of Medicines.—In a country where the laws regulating the sale of drugs by pharmacists are so stringent, it is strange that grocers should be permitted to sell them. We refer to the sale of candies and pastils of santonine by grocers. These famous vermifuge lozenges are a veritable poison, as every physician who is at all familiar with the effects of this powerful alkaloid knows. The law which forbids a pharmacist to sell twenty drops of laudanum without a physician's prescription permits a grocer to distribute santonine thus prepared by the pound. Many serious accidents have occurred in this way and there are other new ones to be found in the *Journal de Médecine de Paris*. Dr. Leo in a valuable article on the subject also cites several. The same may be said of poppyheads, of which decoctions are

imprudently made as sleeping-potions for children and invalids, not only in the country but even in Paris.

The Leagues of Paris.—Leagues seem to be the order of the day. A short time ago the league against cancer was founded by the late Professor Verneuil, Professor Duplay, and others. There were for a time many meetings and papers on the subject, but nothing has been heard of it for some time, although it is still in existence and good work is undoubtedly being done. Individuals too weak to resist by themselves form leagues; that is very natural, but there is danger of going to the other extreme. In the famous Latin Quarter the students of the Faculty of Paris have founded a league against alcohol, the president of which is Dr. Drain, the neurologist. Then there is the league against the abuse of tobacco. Now, if we had a league against making a noise in the streets and against cocottes, the drinking, smoking, and frolicking Quartier Latin would be turned into a sort of austere necropolis, given up to the promenades of water-drinkers and young stoics *fin-de-siècle*.

Appropriation for Laboratories.—M. Audiffred has proposed in the French parliament an appropriation of 250,000 francs for laboratories of investigation, and it is to be hoped that the proposition will be carried. The official laboratories, from which all the best work comes, are often insufficiently supplied with what is really necessary. Moreover, further working-space is needed, as never before were there so many medical students in Paris and never before were the laboratories so crowded. In the École Pratique, where the courses of operative surgery and dissection take place, there has been during the winter just passed a positive dearth of cadavers, something very unusual indeed. The minister of war decided on March 17th that the laboratory of chemistry of the Hôtel des Invalides should be attached to the administration of the service of public health and should have henceforward the name of Laboratory of the Technical Committee of Health. The government seems to be fully alive to this vital question when it can be claimed to-day that battles are won in the laboratory.

The Health of Paris.—The service of municipal statistics has just issued its bulletin for the week—the twelfth week of 1896 according to their reckoning. There were 972 deaths instead of 1,001 during the preceding week, and instead of 1,155, the ordinary average at this time of year. It will be seen then that the sanitary condition of Paris continues satisfactory. Epidemic diseases are rare: typhoid fever caused 7 deaths instead of 20, the average; scarlet fever 3, or just the average number; whooping cough 5 instead of 10, the average; measles 10 instead of 19, the average. There were no deaths from small-pox. Diseases of the respiratory organs and phthisis, as always, were most fatal, there having been 146 deaths from bronchitis, pneumonia, broncho-pneumonia, and pulmonary congestion, and 194 from phthisis, both inferior to the average. Last week there was a slight recrudescence of the grippé, but the cases were all mild and only two deaths occurred.

The Chamber of Deputies and the Doctors.—Until quite recently the tax upon doctors practising in Paris was one-fifteenth of the amount of rent paid. The Chamber of Deputies not long ago passed a law, which has now come into force, assessing all practising physicians one-twelfth of the amount of rent paid. This is called a "patente" and is for the right to practise. The onerous law was passed in spite of an earnest protest by the profession at large, and in spite of the fact that there are many regular physicians in the Chamber of Deputies—some of whom still practise. The bond of confraternity seems to have been dissipated in the political atmosphere of the Chamber, where a fresh tax or increase of an old one and more

money are equally popular. Instead, therefore, of getting the original tax expunged, so that physicians could practise without let or hindrance, they only find themselves more handicapped than ever, and that too by members of their own profession.

A POSSIBLE EXPLANATION OF SUDDEN DEATH AFTER THE ADMINISTRATION OF DIPHTHERIA ANTITOXIN, APPLIED TO THE DEATH OF THE CHILD OF DR. LANGERHANS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I published in the MEDICAL RECORD of October 19, 1895, a note on the use of carbolic acid as a preservative of diphtheria antitoxin, in which, from my experience in the technique of the preparation of the antitoxin, together with a study of some animal experiments, Dr. Kortright's case, and the literature of carbolic-acid poisoning, I concluded that carbolic acid was too dangerous a substance to use.

The announcement of Dr. Langerhans, of Berlin, that "his son, aged twenty-one months, died suddenly while in perfect health, in consequence of an injection of diphtheria antitoxin," caused me to endeavor to ascertain whether the antitoxin used contained carbolic acid and by whom the antitoxin was prepared.

I sent a cablegram to Dr. Langerhans on Monday afternoon to ascertain these facts. To-day (Tuesday) I have received a reply in which he stated that the antitoxin employed contained carbolic acid and that it was prepared at the Hoechst Farbwerke.

The autopsy as reported in the New York *Sun* of yesterday gave a negative result. This was to be expected, as congestion of the brain, meninges, lungs, liver, and spleen may be the only sign present when a small fatal dose of carbolic acid has been hypodermically injected.

"The minimal fatal dose of carbolic acid is not known" (H. C. Wood, "Treatise on Therapeutics," p. 686, 6th ed.). This I have confirmed experimentally on animals and, moreover, have found the minimal fatal dose to vary.

The amount of carbolic acid employed as a preservative in a ten-cubic-centimetre dose of diphtheria antitoxin is ten cubic centimetres of a five-per-cent. solution. This is equivalent to 0.05 gram, or between three-fourths and four-fifths of a grain of carbolic acid.

The minimal dose for adults is usually considered as one grain, or 0.06 gram. Age modifies the dose. H. C. Wood (*l. c.*, p. 22) recommends the rule of Dr. Young, which, allowing the above-given dose for an adult, would for a child of two years make the dose of carbolic acid one-seventh of a grain. Dr. R. O. Cowling (*American Practitioner*, vol. i.) and Professor Clark (*Boston Medical and Surgical Journal*, 1872) give rules which result in the same proportion.

These deductions, applied to the child of Dr. Langerhans, who was twenty-one months of age, would seem to indicate that he had received about five times the safe dose, and, inasmuch as the minimal fatal dose is unknown, perhaps a fatal dose.

I am aware that a great number of patients have been injected with diphtheria antitoxin and that no ill effects have been reported. Among these, however, are a large number who received antitoxin preserved with camphor and other harmless substances. I have met with no case among this latter class which I could include in this explanation. Moreover, it may be urged that if this explanation were true more cases would have been reported.

It is evident from the above explanation that, if the fatal dose be unknown and variable, in the great majority of cases with ill results the relation of cause and effect is much obscured; also that, the effects of the diphtheria toxin must be excluded, and that it is only such rare cases as those of Dr. Kortright and Dr. Langerhans, which seem to have no ordinary explanation, that can demonstrate the explanation here given. I hope to be able shortly to complete an experimental investigation on the possible causes of sudden death after the administration of diphtheria antitoxin.

C. B. FITZPATRICK, M.D.

5 EAST THIRTIETH STREET, NEW YORK,
April 14th.

Therapeutic Hints.

Spurious Iodoform Gauze containing but one-sixth per cent. of iodoform instead of twenty-five per cent. as called for on the label, has been put upon the market, according to the *Apotheker Zeitung*. Auranthin is used to give to the gauze a bright yellow color.

Ulceration of the Cornea resulted favorably in forty cases treated by Dolgénkov (*Iratz*, No. 48, 1895) with a few drops of a fifty-per-cent. lactic-acid solution. Inflammation and photophobia disappear, and an eschar which forms falls at the end of three or four days.

Camphorated Salol applied on cotton to boils and carbuncles and covered with one of the impermeable protectors diminishes pain and decreases swelling.—BOWEN.

Cystitis.—

R Guaiacol	5
Iodoform	I
Sterilized olive oil	100

S. Inject one or two grams into the bladder once or twice daily in painful cystitis and tuberculosis.

—COLIN.

Sternutation. Prolonged sneezing may be checked by injecting spirit of camphor well back into the nostril.—STEWART.

Uterine Leucorrhœa.—Dr. Lirola (*Semaine Médicale*) recommends the following:

R Tannic acid	ij
Pure alcohol	i.
Beechwood creosote	i
Distilled water	viii.

Dose, a tablespoonful in a quart of warm water to be used as a vaginal injection three or four times a day.

How to Remove the Disagreeable Taste of Cod-Liver Oil.—Pavesi's method is to take four hundred grams of oil, twenty-eight grams of roasted and ground coffee, ten grams of pulverized animal boneblack. Heat this mixture to 60° C. in a closed receptacle for fifteen minutes. Let it stand for two or three days, shaking occasionally, and then filter. This leaves a limpid amber oil with the perfume and taste of coffee. Another way is to add to one hundred grams of oil one gram of essence of eucalyptus. *Gaz. Médicale de Liège*.

Acne. Boeck says (*Annales de Dermatologie*) dolphin oil inhibits the growth of bacteria in the skin, and consequently he finds the following useful:

R Camphore	0.30
Acidi salicylici	0.50
Sulphuris precipitatus	10
Zinci oxidum	2
Saponis	1
Olei delphini	12

M. Make the application each night; wash the face in the morning with soap and warm water.

Society Reports.

TRI-STATE MEDICAL SOCIETY OF IOWA, ILLINOIS, AND MISSOURI.

Fourth Annual Meeting, held in Chicago, April 7, 8, and 9, 1896.

THE society met at the Great Northern Hotel under the presidency of Dr. R. H. Babcock, of Chicago.

Antitoxin and Serum Therapy.—After the transaction of miscellaneous business the PRESIDENT'S address was read. He selected for his subject antitoxin or serum therapy. He traced the efforts that had been made to combat tuberculosis by means of serum therapy, telling of the first discovery that certain animals possess comparative immunity from the disease. Detailing several experiments, he said a more intelligent use of tuberculin showed that the early failures were due to its injudicious employment in too large doses. He next passed on to a personal trial of the remedy, citing the case of a young woman of twenty-one years, whose sister had died of pulmonary tuberculosis and in whom well-marked signs of inactive disease existed in the right apex. The administration of antiphthisin for two months was followed by a gratifying disappearance of the malaise, nervousness, and occasional slight cough. He also treated a male, aged thirty-four, with satisfactory results.

Dr. von Ruck had furnished the speaker with advanced sheets of a report, soon to be published, of one hundred and eighty-two cases of consumption in all stages treated with tuberclocidin and antiphthisin, in which recovery was obtained in thirty-two per cent. of the cases, arrest or marked improvement in thirty per cent., and some improvement in sixteen per cent.

Special Education as a Means of Treatment in Chronic Neurasthenia.—By DR. J. F. PERCY, of Galesburg, Ill. Neurasthenia, he said, is considered the result of an imperfectly used and therefore improperly developed nerve organization. In his city there is an ably conducted kindergarten normal school, and when he has a neurasthenic woman he sends her, if possible, to this school to take the normal course there. The result has been that every case so treated has recovered. In one case cited the right ovary was buried in a mass of exudate beneath the uterus. Electricity and pelvic massage were resorted to for over a year with but little, if any, appreciable result. All treatment was stopped and the woman sent to take a kindergarten normal course, with the result that she is well to-day, so far as any morbid mental phenomena are concerned.

Cancer of the Uterus Complicated by Pregnancy, with Indications for Operation was the title of a paper read by DR. A. H. CORDIER, of Kansas City, Mo., in which the author reported a successful case of vaginal hysterectomy in a woman thirty-two years of age, the uterus being three months pregnant.

In twenty-seven cases tabulated by Dr. Vander Veer, of Albany, five patients had died during labor undelivered, nine had died during the puerperal period, in three cases the results were not mentioned, and ten had recovered, the mortality to mothers being sixty per cent. Another author had reported thirty-four cases of cancer of the uterus complicated by pregnancy, with a mortality of fifty-two per cent.

The author drew the following deductions: (1) Cancer of the cervix uteri, if left without surgical interference, always kills. (2) The disease in most instances is primarily a local process. (3) Early hysterectomy will cure a considerable percentage of these cases. (4) The microscope, while a great diagnostic aid, is not infallible in its findings. (5) The experienced surgeon is warranted in resorting to hysterectomy,

even in doubtful cases. (6) All malignant pregnant uteri should be removed when seen, before the disease has advanced beyond the period of a probable cure.

DR. RYAN, of Galesburg, cited an uncomplicated case of cancer of the cervix which occurred in the hands of another practitioner. The cervix was amputated; the patient was four months advanced in pregnancy. Following the operation she went to full term and the child was delivered without difficulty.

DR. L. H. DUNNING, of Indianapolis, said that if he should find hardening of the cervix and the development of a neoplasm with the presence of discharges sanguineous or offensive in character, even though the microscope failed to reveal positively the existence of malignant disease, he should pursue the course recommended by the essayist.

DR. RUFUS B. HALL, of Cincinnati, thought the whole matter hinged upon diagnosis. When the diagnosis was accurately made it was perfectly clear what should be done. He favored total extirpation, believing that high amputation should only be performed in exceptional cases.

DR. D. C. BROCKMAN, of Ottumwa, Ia., emphasized the importance of early diagnosis. The general practitioner does not understand the importance of irregular hemorrhages occurring in women approaching the menopause, and prescribes a placebo when a radical operation is needed.

DR. BYRON ROBINSON, of Chicago, concurred with the essayist that the microscope alone is insufficient in many cases to enable surgeons to make an accurate diagnosis of malignant disease of the cervix. More stress should be laid upon the clinical history of the case.

Diffuse Pelvic Inflammation.—A paper on this subject was read by DR. L. H. DUNNING, of Indianapolis. The author reported five cases in which vaginal hysterectomy was resorted to for inflammatory disease of the uterus and appendages. In all of the cases, except one, the uterus on removal was not found to be markedly diseased beyond a glandular endometritis. In the two cases in which the uterus and appendages were fixed the operation was most difficult. The uterus in either case was only slightly diseased. The chief pathological lesions were double pyosalpinx and pelvic peritonitis. The operation would have been easy and the results quite as good by the abdominal method. In these cases the appendages were much more inaccessible and less open to ocular inspection than in the abdominal operation. In his experience in clamp cases the pain after vaginal hysterectomy is greater the first two days than after celiotomy. The systemic disturbances, as evidenced by the temperature and pulse rate, do not vary much in the two methods. The temperature after vaginal hysterectomy is lower the first three or four days but is higher after six or ten days, when the sloughs begin to give way. In two cases in which ligatures were employed instead of clamps, abscesses in the stumps of the broad ligament followed, retarding the recovery of the patients. Many cases of abdominal section were done in the hospital during the same time, and in none of them did abscess appear. In one case of the five prolapsus of the vaginal walls appeared a few weeks after the patient began to walk around. This was a ligature case. Such a prolapsus he had never witnessed in a forceps case. In three of the cases the same pain and nervousness followed the recovery as is sometimes witnessed in cases of abdominal section. In two of the cases the pain and nervousness passed off after several weeks, as they usually do after abdominal section.

DR. RUFUS B. HALL said that women should be educated up to the point of avoiding septic infection, suppurating tubes and ovaries, and the young men should likewise be educated to avoid gonorrhea in order to prevent infecting their wives in future years.

DR. T. J. WATKINS, of Chicago, said that all large pus collections in the pelvis that can be opened and efficiently drained without entering the peritoneal cavity should be treated by incision and drainage through the vagina or above Poupart's ligament. Vaginal hysterectomy should be the operation of election in old backward displacements in which the uterine appendages are destroyed by suppurative disease.

Dysuria in Women.—A paper was read by DR. O. B. WILL, of Peoria, on this subject.

DR. E. O. SISSON, of Keokuk, Ia., followed with a paper entitled "Ulcerative Inflammation of the Cornea." He first dwelt upon the etiology, then passed on to the subdivisions of keratitis suppurativa. Symptomatology and complications were next considered. In the treatment of corneal ulcers the author reiterated the methods laid down in the several text-books.

Pylorectomy in America.—By DR. ALEX. HUGH FERGUSON, of Chicago. The author reported a case of carcinoma of the pylorus upon which he had successfully operated. He recommended pylorectomy for carcinoma of the pylorus for the following reasons: (1) Medical treatment offers a mortality of one hundred per cent. within twelve or eighteen months. (2) Pylorectomy promises a possible cure. In nineteen per cent. of over nine hundred cases dying with cancer of the pylorus no adhesions whatever were found after death; starvation took place before the carcinoma had reached the peritoneum. There would be good prospects of curing most of these. Recovery follows the operation in about fifty per cent. of the cases. By timely interference many cases can be saved that now go on to secondary infection and are doomed.

After opening the abdomen, Dr. Ferguson recommends the performance of pylorectomy thus:

1. Liberate the duodenum from the pylorus, unite its distal cut end to the posterior surface of the stomach with Murphy's button, invert the proximal cut end toward the pylorus, and close with sutures. The great advantage of completing the gastro-duodenostomy first is that the operation can be safely stopped at this stage should the patient show signs of weakening, the abdomen be at once closed, and the removal of the pylorus be left for a second operation.

2. Separate the stomach from the pylorus and close it rapidly with sutures. Should the patient now present alarming symptoms, the surgeon should again cease operating and leave the pylorus *in situ* in the mean time. It would, of course, be necessary to fasten it in the abdominal wound and drain it externally, which would only facilitate its extirpation at another time.

3. Remove the cancerous pylorus. Spend no time in trying to use interlocking ligatures, but apply forceps after forceps and cut the mass away. This done, the application of ligatures can be effected more expeditiously.

Local Treatment of the Eye was the title of a paper contributed by DR. DUDLEY S. REYNOLDS, of Louisville, in which he said that the local treatment of this organ was as much in need of reform and readjustment as any other department of surgery, for there had been little change in prevailing custom for nearly a hundred years. He considered the yellow oxide of mercury very valuable as a local application in nearly all forms of ulceration or abrasion of the cornea and conjunctiva. The tension of the eyeball should be noted in every case of injury, and, if found slightly increased, a solution of eserine should be instilled, a saline purgative administered, and, if the increased tension be accompanied by a sense of pain on pressure upon the globe, it is best to begin with salicylate of sodium or ammonium at once. Hot ablutions are often of great value in cases of irritation of the iris and ciliary body, whether due to constitutional or to local causes.

Criticisms of Sero-Therapy.—DR. PAUL PAQUIN, of St. Louis, Mo., read a paper entitled "Observations on some Criticisms of Sero-Therapy." No department of therapeutics, he said, had called forth so much criticism as sero-therapy. These criticisms had been of two kinds—those based on scientific problems of biology, and those based on clinical effects and results.

As to the beneficial effects of serum, he thought these depend unquestionably in a great measure upon increased phagocytosis. The serum increases the white cells, whose duty it is in part to destroy micro-organisms in tissues and their toxins, probably by a process of cellular digestion, or rather a diastatic neutralization. In a tuberculous man of thirty-five years, in whom the white cells were less than 16,500 per cubic millimetre, they were increased to over 40,000 in seventeen days by the daily injection of two cubic centimetres of anti-tubercle serum. The author obtained a similar result in a rabbit in which he had injected the Roux anti-tubercle serum daily for three days, the dose being one cubic centimetre.

DR. FRANK ALLPORT, of Minneapolis, read a paper in which he pointed out the relations which should exist between ophthalmologists and opticians. He advanced strong arguments in favor of licensing opticians to fit glasses. The fitting of glasses was not a trivial affair, but necessitated in many instances a thorough examination of the eyes by a properly equipped, specially trained medical practitioner.

The Operative Treatment of Jacksonian and Focal Epilepsy, as Illustrated by Selected Cases.—By DR. CHARLES B. NANCREDE, of Ann Arbor, Mich. He said the cases reported demonstrated what had been the experience of Horsley, Keen, and other surgeons; namely, lack of permanency in results. The removal of the discharging lesion in cortical and Jacksonian epilepsy could only be regarded as palliative. The earlier the operation was done after the disease had become established, the longer the immunity. It is possible that if trephining were resorted to early, the operation in a few instances might prove curative, if a reliable method were devised to lessen the inevitable scar and to prevent adhesions between the membranes and brain.

Some Needed Reforms in Medicine.—This was delivered by DR. JOSEPH M. MATHEWS, of Louisville. He first dealt with specialism. Professors in medical colleges should impress upon the minds of students that thorough preparation is necessary to be a specialist, and unless this is done specialism would be brought into disrepute. No man can be a specialist in any department of medicine who has not fitted himself and has had experience in general practice.

Reform is needed in the appointment of medical men to medical institutions. Too often petitions are circulated and signed in favor of men without considering their professional qualifications.

Expert testimony should be raised to a higher plane, and those who testify as experts should receive adequate compensation.

The old rule that applied to consultations does not hold good to-day. At the present time a patient belongs either to the physician or to the specialist, and not to both alike. When a specialist recognizes that a patient does not require his special attention he should call a physician. *Per contra*, when a physician recognizes that a patient needs special attention he should give the patient to the specialist.

As to the Code of Ethics, this document needed no defence from him. Not a man or woman could raise any objection to what is taught therein.

The State Board of Health of Kentucky had succeeded in driving out of the State within the last two years over eight hundred and sixty quacks. This was accomplished by the concerted action of the medical

profession and the representatives in the State legislature.

Early Operations in Appendicitis.—DR. R. HARVEY REED, of Columbus, O., contributed a paper on "Some Practical Reasons for Early Operation in Appendicitis." The following conclusions were drawn: (1) That the appendix vermiformis is a useless rudiment. (2) That chronic catarrhal appendicitis is always dangerous and liable to be followed at any time by hazardous and even fatal results. (3) That medical treatment is of little or no permanent value in this class of cases. (4) That the only safe and reliable method of treating chronic catarrhal appendicitis is the prompt amputation of the appendix. Cases were then reported illustrating the importance of early operative interference and the arguments of eminent surgeons advanced in its favor.

Surgical Tuberculosis.—DR. D. C. BROCKMAN, of Ottumwa, Ia., followed with a paper entitled "Observations in the Treatment of Surgical Tuberculosis." He called attention to three remedies which he had used in the treatment of this disease—guaiacol internally and iodine trichloride and iodoform emulsion locally. He thinks guaiacol is an efficient remedy for the septic condition which accompanies tuberculosis, when judiciously used. Iodine trichloride he uses in vesico-tuberculosis. In the management of tuberculous abscesses there is no treatment that could compare with the use of iodoform emulsion.

DR. ELMER LEE, of Chicago, read a paper on the "Treatment of Pneumonia without Drugs." The author had recently instituted in his practice a sprinkling bath, which he illustrated. Pneumonia cases treated by scientific hydratic measures are convalescent at the end of the first week. Complete recovery is proportionately shortened. It is the author's belief that this method of treatment is the quickest, surest, and best management of pneumonia.

Conservative Surgery in the Treatment of Hemorrhoids.—By DR. JOSEPH B. BACON, of Chicago. He had found in looking over his records that but a very small per cent. of his operative cases had been purely internal or external hemorrhoids. Patients who were suffering or bleeding sufficiently to cause them to seek medical advice were those who had a mixed form of piles, in which the anastomosing vessels connecting the external and internal hemorrhoidal veins had become varicose, and these dilated veins pressed upon the sensory nerve filaments over the inner border of the external sphincter muscle, causing pain and prolapse of the internal hemorrhoids. A segment of the varicose system of veins must be removed, one segment on each side of the anus being sufficient. Remove those hemorrhoids that are causing the discomfort together with the external or skin tags, and the patient is cured, and only a small surface of either skin or mucous membrane had been disturbed. The ligature, clamp, and cautery, or crushing method, according to the choice of the surgeon, would answer the purpose.

Leucocytosis—Its Relation to Modern Therapy.—This paper was read by DR. THOMAS O. SUMMERS, of St. Louis, Mo.

DR. ALEXANDER C. WIENER, of Chicago, exhibited cases of spastic torticollis treated with an extension apparatus combined with corsets.

DR. GUSTAV FUETTERER, of Chicago, described a method of treating gonorrhoeal infections of the knee-joint by injections of oil of sandalwood. He employs the best preparation of this kind made and his results have been gratifying.

Clinics.—Clinics were given at the Post-Graduate Medical School by Dr. J. B. Murphy, before the members of the society: at Rush Medical College by Drs. J. H. Dtheridge, Fernand Henrotin, and Nicholas Senn.

The following officers were elected for the ensuing year: *President*, Dr. A. H. Cordier, Kansas City, Mo.; *First Vice-President*, Dr. Hugh T. Patrick, Chicago, Ill.; *Second Vice-President*, Dr. H. C. Eschbach, Albia, Ia.; *Secretary*, Dr. George W. Cale, St. Louis, Mo.; *Treasurer*, Dr. C. S. Chase, Waterloo, Ia.

St. Louis was selected as the place for the next meeting.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, April 9, 1896.

WALTER LESTER CARR, M.D., CHAIRMAN.

Some Considerations of Rachitis.—DR. A. JACOBI, in the course of a paper on rachitis, referred to the view held by several authors that rachitis was dependent upon syphilis in the parents or child, but in his opinion the relationship, if any existed, did not differ from that existing between rachitis and any constitutional condition which reduced the general health. It was a mistake committed by some physicians that they looked for the manifestations of rachitis only in the bones. In reality it spared few tissues; the muscles were weak and flabby, the spleen was enlarged, the lymph organs were likely to be altered, there was leucocytosis. He had several times seen grave rachitis complicated by pseudo-leukemia. The deposition of lime in the bones in rachitis was diminished or altered, and there might even be resorption and softening of parts which had already become calcified. In infants the first change in the bones was seen in the cranium, more especially in the occipital region and along the sagittal suture; next along the lambdoidal, for at this age the brain with its osseous envelope was undergoing most rapid development. The occipital portion of a skull was presented, in which many spots showed absence of bony deposit when held up to the light. The increased size of the arteries in rachitis resulted in slackening the circulation and contributed to swelling of the viscera, to which they were already predisposed by the succulence and expansibility of their tissues. The cerebral murmur which could be heard in these patients seemed to be caused by the large carotid artery being compressed in its bony channel before it entered the cerebral cavity. If the health were restored and the disease arrested, the increased size of the brain might leave the children brighter and smarter than their schoolmates. On the other hand, the cranial tabes might lead to internal or external hydrocephalus. While a certain amount of hydrocephalus was not unusual, it seldom went to the second stage. The changes in the long bones in cases terminating favorably might result in increased size and strength.

Hypertrophy of the heart was likely to be diagnosed in rachitis, but the cardiac dullness was unusual in extent simply because the thorax was out of shape, the chest being either triangular, quadrilateral, or flattened, and the heart touched a larger surface than in the normally elliptical chest.

There was no direct relation between rachitis and tuberculosis, yet rachitic children were apt to become tuberculous, no matter what the cause of the rachitis might be. There were several reasons for this: the rachitic chest was narrower than normal, the lungs had less space for expansion, there was consolidation of the sternum; interference with respiration and sanguification led to peribronchial hyperemia, epithelial and catarrhal changes; foreign bodies, including microbes, entering the bronchi were not expelled. Thus these patients had frequent attacks of bronchitis,

perhaps lobular pneumonia and tuberculosis. Swelling of lymphatic glands was secondary, and was rarely seen in uncomplicated rachitis.

Nervous symptoms were frequent. Insomnia was common, and many patients slept better carried about on the arm, for as soon as they were laid down the brain became hyperemic. Sometimes they were bad-tempered to the degree of moral or intellectual insanity. Hydrocephalus had been mentioned. A large proportion of cases of laryngismus stridulus were due to cranial tabes, although this was doubted by some. Commenting on the three phenomena said to be characteristic of tetany—the electrical, the facial, and the popliteal phenomena—Dr. Jacobi said that all three often disappeared under antirachitic treatment. Rachitic pseudo-paralysis he attributed to muscular deficiency. When nystagmus existed it was usually bilateral, and there was apt to be motion of the head in the same or opposite direction. Scoliosis was very common, and this was favored by the habit of carrying the infant in one position on the arm and the malposition assumed in school. Resurrection was preached only from the pulpit, while nothing was said about that effected by fresh air, hygienic conditions, and proper food.

Renal disorders were not at all uncommon. Constipation which could not be accounted for in other ways should excite a suspicion of rachitis, and unless relieved at once by antirachitic treatment the diagnosis would be confirmed after a while by the appearance of other symptoms of rachitis.

The use of Pasteurized and modified milk had been attended with certain advantages, but it was a mistake to suppose that this alone would prevent rachitis and preserve good health. The author did not enter far upon the subject of treatment, but referred incidentally to the indication for phosphorus and change of food.

A Case of Rachitis in an Infant Breast-Fed.—DR. H. D. CHAPIN presented a child, then two years old, which had been under his observation a year or longer, but the parents were very poor and ignorant, and allowed the child to remain in their narrow rooms, almost entirely deprived of light and change of air. The result had been that in spite of having breast milk it had developed rachitis, which manifested itself more especially in the bones of the thorax, in pseudo-muscular paralysis, atelectasis, and some kyphosis.

DR. AUGUST CAILLÉ said we had heard from the author about the association of rachitis, syphilis, and tuberculosis—three chronic ailments which were met in various manifestations almost daily. Syphilis and tuberculosis were due to specific microbes, while rachitis had no such causative factor, but was a pronounced type of malnutrition. Syphilis and tuberculosis, if they did not kill in early life, might in later life seriously damage the organism, whereas rachitis showed a decided tendency to heal.

He had that day seen a case of pseudo-paralysis due to rachitis which had been mistaken for paralysis of nervous origin, but careful examination would usually show signs of rachitis and the true nature of the muscular weakness. Physicians ought also to be careful not to mistake acute epiphysitis of rachitic origin for rheumatism. Both were attended by pain on movement, but the presence of cranial tabes, sweating, and constipation would show rachitis. Most cases of laryngismus stridulus which he had seen had been in rachitic children.

The family physician should not alone see that the child was properly nourished after birth, but should give directions to the pregnant woman to partake of sufficient albuminous and other food. Taking the mother's milk was not in itself proof that the infant was being properly fed, for analysis sometimes showed

that such milk did not contain the proper proportions of fat, albuminoids, and other ingredients. It was always a question whether the infant should continue to nurse after the mother began again to menstruate, for it was known that during menstruation the milk was changed. The milk should be examined both chemically and microscopically.

DR. CHAPIN said he did not mean in presenting his case to say that the baby had got absolutely the right kind of food, but simply that the preponderating factor in producing the rachitis was bad surroundings, and that this would produce rachitis as well as bad food. It was not true, either, that we could by analyzing food say positively that it would agree with the child. Food contained a certain vital element which no analysis had yet revealed, so that an infant might thrive on a given kind and not on another, which so far as we could determine by analysis was quite similar. Incipient rachitis was common in this city among all classes, although the more advanced cases were seen oftenest in the tenement houses. It was important to strip the patient of all clothing during the examination. In most or all cases there was some enlargement of the costal articulations. These patients would sweat at the head while the body was hot and dry, they kicked off the bedclothes, the equilibrium of the nervous system was easily disturbed, they were liable to convulsions, the teeth might appear too early or too late, there was often persistent cough, indigestion, etc. Rachitis aggravated other ailments, some of which were named.

Rachitis a Varying Picture.—DR. F. M. CRANDALL said he had once had occasion to see a great many cases of rachitis, and had been surprised to find that it showed itself so unequally in different parts of the body in the different cases: in one it manifested itself most in the cranium, in another in the joints, in others in the chest. It was easy to overlook a mild case unless it were examined in a critical way. There was never a greater error than the belief that rachitis was simply a disease of bones. The muscular system and nearly all of the organs of the body were affected. Fat was a most important element in the diet of young children, and was almost always deficient in quantity in the mother's milk in cases of rachitis. The value of cod-liver oil was well known.

DR. A. B. JUDSON remarked that the absence of deformity of the legs in Dr. Chapin's case might be accounted for by the fact that the child had never put its weight upon them. As an example of great strength in those who had had rachitis in early life, he mentioned the case of a powerful sailor whose legs were so deformed that he was called "duck toe."

DR. ACHILLES ROSE mentioned the relationship, referred to by several authors, between rachitis and scurvy.

The Chairman, DR. CARR, emphasized the fact that nursing a child was not proof that it was receiving suitable food; also the fact that rachitis might show itself in the muscular and nervous systems and other organs as well as in the bones.

DR. JACOBI said that when he had first seen modified milk used by Dr. Rotch he was so favorably impressed with it that he took steps to have it introduced into New York by the Boston firm. There could be no doubt that such milk and that which was Pasteurized had done much to check intestinal disorders. But certainly it was not all that we would wish as an artificial food, for he had seen quite a number of cases of rachitis in babies fed upon it. This had to be prevented by the addition of oatmeal or barley and animal broth. If the child were constipated, give oatmeal; if diarrhoea existed, give barley. He did not allow a baby to go beyond the sixth month without animal broth. The first year of life was the making of

the man or woman, for it was this period which largely determined the future growth of the viscera as well as of the bones and muscles.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 11, 1896:

	Cases.	Deaths.
Tuberculosis.....	259	119
Typhoid fever.....	3	0
Scarlet fever.....	120	7
Cerebro-spinal meningitis.....	3	5
Measles.....	493	28
Diphtheria.....	254	30
Small-pox.....	0	0

"Case for Operation" is an intelligent partial diagnosis which should be made in some cases. I do not believe in carelessly opening the living human body as a child breaks his toy, just to see "what's inside," but if there are logical grounds to suspect that there is something inside which ought to come out, delay can rarely be productive of good.—LILIENTHAL.

Typhoid.—Every fatal case of typhoid is, in fact, a violent death, an example of water poisoning, and should be the subject of sanitary inquest.—ERNEST HART.

DR. G. H. CANTYLER died recently in St. Petersburg at the age of ninety years. He was for fifty-six years director of the Children's Hospital in St. Petersburg.

Books Received.

While the MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

THE PRACTICE OF MEDICINE. By Marvin A. Curtis, M.D. 12mo, 367 pages. Boericke & Tafel. Philadelphia, Pa. Price, morocco, \$2.00.

DIETS FOR INFANTS AND CHILDREN IN HEALTH AND DISEASE. By Louis Starr, M.D. 12mo. W. B. Saunders. Philadelphia, Pa. Price, \$1.25.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY, SEVENTH SESSION, 1895. 8vo, 222 pages, illustrated.

ELECTRICITY IN ELECTRO-THERAPEUTICS. By E. J. Houston and A. E. Kennelly. 12mo, 402 pages, illustrated. The W. J. Johnston Co. New York. Price, \$1.00.

CLINICAL LECTURES ON ABDOMINAL SURGERY AND OTHER SUBJECTS. By Charles T. Parkes, M.D. Edited by Dr. A. J. Ochsner. 8vo, 477 pages, illustrated. The W. T. Keener Co. Chicago, Ill. Price, \$4.00.

THE BLOOD CORPUSCLES IN DIPHTHERIA; WITH ESPECIAL REFERENCE TO THE EFFECT PRODUCED UPON THEM BY THE ANTITOXIN OF DIPHTHERIA.*

By JOHN S. BILLINGS, JR., M.D.,

ASSISTANT BACTERIOLOGIST, NEW YORK HEALTH DEPARTMENT.

THE following investigations were instituted primarily in order to determine, if possible, the effect produced upon the blood by the subcutaneous injections of diphtheria antitoxin and its accompanying horse-blood serum. Especial attention has been paid to the red corpuscles, as the greater part of the work done by previous observers upon the blood in diphtheria, has been limited to the leucocytes. The question as to the etiology of the leucocytosis observed in diphtheria and the source whence it is derived, has not been touched upon. Those interested in that subject, together with the question of hyper- and hypoleucocytosis, are referred to the articles by Ewing and Morse hereinafter quoted. An article by Ewing on "Toxic Hypoleucocytosis" (*New York Medical Journal*, March 2, 1895) also gives an excellent review of the subject, together with some original experiments.

The investigations of the blood in diphtheria have been comparatively few, and, as stated, have been confined largely to studies of the leucocytes.

Bouchut in 1868 was the first to note an increase in the leucocytes in the blood in diphtheria. The first published observations were those of Bouchut and Dubroisay.¹ They reported twenty-four cases of diphtheria and membranous croup, and found a distinct diminution in number of the red corpuscles in all their cases.

In seven the count was below 4,000,000 per cubic millimetre, and the average of all the counts in all the cases was 4,461,543 per cubic millimetre. As this last figure doubtless included the counts made at the beginning of the illness as well as those made in convalescence, the diminution noted at the height of the disease must have been considerable. Unfortunately for comparison, the authors gave only one average count for each case. The leucocytes were found to be markedly increased in number in almost every case.

Cuffer² made counts of the red and white corpuscles in fifteen cases of diphtheria. In all of his cases but one the number of red corpuscles was above 5,000,000 per cubic millimetre. He therefore concludes that there is little if any diminution in the number of red corpuscles in diphtheria. On examining his table, we find that a second count was made in only one case; in that one the red corpuscles fell over 1,000,000 per cubic millimetre in two days. It is also to be noted that in three of his cases the red corpuscles reached the remarkable figures of 7,451,000, 7,251,000, and

7,852,980 per cubic millimetre respectively. So that it is an open question whether his counts are not all from one to two million per cubic millimetre higher than they should be. This would make the majority of his cases show an anæmia. He found the leucocytes above normal in only six out of the fifteen cases. This is curious, considering the high counts of the red corpuscles above referred to.

Bouchut³ in 1879 made one hundred and seventy-seven examinations of the blood in diphtheria, following some of the cases throughout their course. He did this to confirm his first results, which had been contradicted by Cuffer. He reports only twenty-seven of the one hundred and seventy-seven observations, thinking this number sufficient to uphold his views.

Four cases were followed throughout. In one there was no reduction in the number of the red corpuscles; this was a very mild case. In the other three cases there was a reduction of from 610,000 to 1,100,000 per cubic millimetre. He also reports seven observations in single cases. In all but one of these the number of the red corpuscles was below normal; *i.e.*, 5,000,000 per cubic millimetre. He found the leucocytes to be increased in number in the majority of the cases, and states positively that the degree of leucocytosis is directly proportional to the degree of septicaemia; no septicaemia, no leucocytosis, and *vice versa*. Yet in this very article he reports a fatal septicæmic case showing no leucocytosis; this is directly contradictory to the statement above quoted.

Pee⁴ found a leucocytosis in diphtheria, but not so marked as in simple follicular tonsillitis.

Rieder⁵ noted the presence of a leucocytosis in diphtheria, but doubted the possibility of any knowledge of the same being of prognostic value. In his cases the leucocytosis disappeared promptly when convalescence began.

Reinert⁶ reported one case of diphtheria as follows:

	Reds.	Whites.	Large Leucocytes.	Small Leucocytes.	Hamoglobin.
Third day,	5,050,000	5,763	91	22	92%
Sixth day,	4,398,000	7,700	111	39	87%

A distinct diminution in the number of the red corpuscles and amount of hamoglobin took place between the third and sixth days. It is curious that no leucocytosis was noted. The relative numerical proportions of the various forms of leucocytes was about normal, the smaller forms being twenty and twenty-four per cent. respectively.

V. Limbeck⁷ noted the presence of a leucocytosis in diphtheria, as also did Halla.⁸

Felsenthal⁹ reported the results of the examination of the blood in eight cases of diphtheria. He could make out no reduction in the number of red corpuscles nor any changes in their morphology or staining reactions. He found a leucocytosis in all cases, reaching in one instance the enormous sum of 148,229 per cubic millimetre. He found the relative numerical proportions of the various forms of leucocytes to be the same as in pneumonia; *i.e.*, an increase in the so-called polynuclear forms. The leucocytosis disappeared coincidentally with the inflammatory phenomena. In one

* A Report to H. M. Biggs, M.D., pathologist and director of the Bacteriological Laboratory, Health Department, New York City.

case the leucocytes contained basophilic granulations: these he held to correspond with the "mastzellen" of Ehrlich. This subject will be discussed later.

Gabritschewsky¹⁰ was the first to investigate the effect of the diphtheria antitoxin upon the blood corpuscles. He examined the blood in fourteen cases and found a leucocytosis in all of them. This leucocytosis diminished progressively after the use of antitoxin in twelve cases. In two of the fatal cases the number of leucocytes increased after the administration of the antitoxin.

His most important conclusions are that the leucocytosis of diphtheria can be distinguished from that of many other infectious diseases (how, he does not state) and that a steady rise in the number of the leucocytes is usually of bad omen.

Morse¹¹ examined the blood in thirty cases of diphtheria, only one examination being made in each case. The red corpuscles were normal or above in twenty-one cases; below normal in nine cases. The hæmoglobin was not estimated. A leucocytosis was present in all but four cases, two of the latter being convalescent. Differential counts showed the increase in number of the leucocytes to be chiefly in the so-called polynuclear forms—a simple inflammatory leucocytosis. He believes the leucocytosis to be due to the absorption of toxins and that so many factors enter into the question that no information of prognostic value is to be gained from examinations of the blood.

Ewing¹² reports fifty-three cases of diphtheria which he followed throughout as far as possible. All of these received injections of antitoxin; the number of "units" is given, but not the amount of serum injected. In several instances he has simply given the strength of ten cubic centimetres of the serum, omitting the number of cubic centimetres given. This of course tells us nothing. Of these fifty-three cases, all but four showed a leucocytosis at some time in their course (10,000 per cubic millimetre or above). The four cases in which the number of the leucocytes was normal were all mild and speedily recovered. His differential counts agree with those of Morse and Felsenthal (*l. c.*). In one case the lymphocytes were markedly increased; thirty-two and thirty-five per cent. on two occasions. This the author calls a lymphocytosis. In those cases showing no leucocytosis, the larger mononuclear forms were increased, with a corresponding diminution in the percentage of the lymphocytes. His most important conclusions are as follows:

"In favorable cases, after the injection of antitoxin, the leucocytosis never again reaches its original height." In severe cases "an injection of antitoxin may be followed immediately by rapid hyperleucocytosis or extreme hypoleucocytosis and death." "Antitoxin, within thirty minutes after its injection, causes a hypoleucocytosis," the reduction being chiefly in the uninuclear forms. "The staining reaction of the leucocytes is an accurate measure of the severity of a diphtheritic infection, and variations in this reaction often precede changes in other symptoms." The multinuclear leucocytes in favorable cases after treatment with antitoxin show increased affinity for gentian violet. Absence of this change twelve hours after injection makes the prognosis unfavorable. He also dwells upon the occurrence of "pseudo-eosinophile" granules in the protoplasm of the leucocytes. This subject, together with that of the poor staining of the nuclei, will be referred to later in this report.

As regards the effect of injections of serum upon the blood, the literature of such investigations as are adapted to our purpose is very scanty. The various text-books of physiology speak of the destruction of the red corpuscles after transfusion and even after in-

jection of serum, but no references or experiments are given. The most recent contribution to the subject is that of Chapin.¹³ He investigated the effect of prolonged injections of horse serum upon the number of red corpuscles and percentage of hæmoglobin in rabbits, guinea-pigs, and other animals. He himself says that his experiments are inconclusive, but that serum injections as ordinarily employed in therapeutics have little effect upon the corpuscles.

In the following series of observations three classes of cases were examined; those of diphtheria with and without antitoxin and those of healthy children injected with antitoxin for immunizing purposes. The cases of diphtheria without antitoxin were those reported from the various dispensaries. All of these cases were apparently mild when first seen; otherwise they would have been injected with antitoxin. Several, however, became severe, and in two cases antitoxin was administered because of the severity. The blood counts in these two cases have been omitted. The cases of diphtheria receiving antitoxin were all seen at the Willard Parker Hospital, and thanks are due to Dr. Somerset, the resident physician, for his unfailing courtesy and cordial assistance. The cases which received antitoxin for immunizing purposes were seen at the New York Juvenile Asylum. Several cases of diphtheria had developed there, and all the inmates were immunized. The injections were given by Dr. Studdiford, one of the inspectors of the health department. The antitoxin used in all these cases was that prepared at the laboratories of the Board of Health. The varying amounts and strengths are given in the tables. The regulation Thoma-Zeiss instrument was used for counting the corpuscles. In counting the red cells, the blood was diluted two hundred times with Toison's fluid (sodium chloride 1, sodium sulphate 8, Bower's glycerin 30, water 160, methyl violet .025) and the number of corpuscles counted in one-half the entire number of squares. This was repeated in a second specimen, thus obtaining a fair average. Toison's fluid preserves the shape of the red corpuscles and for a longer time than simple salt solution or any of the diluents advised by other investigators. The large Zeiss mixer was used in counting the leucocytes, the blood being diluted ten to twenty times with one-third per cent. acetic acid, and the number of leucocytes in four entire fields being taken. The acetic-acid solution dissolves away all the hæmoglobin from the red corpuscles, thus rendering them invisible, and brings out the nuclei of the leucocytes quite sharply. In several of the cases the six-per-cent. salt solution tinged with gentian violet as advised by Ewing was used. The nuclei of the leucocytes being stained, they are of course more easily recognizable, but the blood has to be diluted from one hundred to two hundred times in order to prevent the red corpuscles from completely hiding the leucocytes. This of course increases greatly the liability to error. The percentage of hæmoglobin was estimated by means of a v. Fleischl hæmometer, two specimens being taken in each case.

The specimens for microscopical examination were made by the double-cover-glass method and after drying in the air for one to two hours were hardened in one of three ways—by heating for two hours at 140° C. according to Ehrlich, by keeping them for one to two hours in a mixture of equal parts of absolute alcohol and ether, or for the same length of time in a saturated aqueous solution of bichloride of mercury. Each one of these methods was used in every case, and on the whole the alcohol-and-ether mixture gave the best results. In some of the cases the specimens were immediately passed through the flame of an alcohol lamp while still moist, and then hardened as above. The majority of the specimens were stained with a

modification of the triple stain first used by Ehrlich. The writer has found the following to be the best method for its preparation: First make saturated solutions of the following stains in hot distilled water: (*a*) orange green, extra; (*b*) acid fuchsin, extra (Rubin); (*c*) crystallized methyl green. Let them settle for two days and then with a clean dry pipette take of (*a*) 55 c.c. and of (*b*) 50 c.c. Add to these distilled water 100 c.c. and absolute alcohol 50 c.c. After thoroughly shaking the above mixture, add the following solution drop by drop, shaking thoroughly between each drop: saturated solution of methyl green (*c*) 65 c.c., distilled water 50 c.c., and absolute alcohol 12 c.c. Allow the stain to stand two weeks before using and then take from the middle of the bottle with a perfectly dry pipette. It will keep indefinitely, apparently improving with age. To use it, simply put one or two drops on the cover glass and allow to remain for four or five minutes. Wash thoroughly in water, dry between filter paper, and mount in balsam. The above is simply a rough working-formula, and the stain often has to be made up three or four times before it proves satisfactory. It must be made for a definite purpose, and has to be experimented with in order to make it suitable for such purpose. For instance, if the object of study be chiefly the red corpuscles, the proportions of methyl green and acid fuchsin should be relatively small: the red cells then take on a clear orange stain and changes in their staining-reaction can be more readily made out. To study the leucocytes, on the other hand, the amounts of the two stains above mentioned should be relatively large in order to bring out the nuclei and granules. In certain cases the specimens were also stained with eosin and methylene blue, methylene blue alone, eosin-hæmatoxylin (Ehrlich's acetic-acid mixture), Ehrlich's dahlia solution and safranin. Further reference to these will be made later on.

The estimation of the relative numerical proportions of the various forms of leucocytes was made by counting a certain number of leucocytes in specimens stained with the above-mentioned triple stain. From two hundred and fifty to one thousand leucocytes (an average of five hundred) were counted in each case, the counting of the same leucocyte twice being

avoided by the use of the mechanical stage. This is a tedious process it is true; an objection often urged against it. But so far no other reliable method for accomplishing the same purpose has been advanced. Elzholtz¹⁴ has proposed a method which is theoretically perfect. He uses the large Zeiss mixer, diluting the blood ten times only. His solution or solution dissolves away the majority of the red corpuscles, and the leucocytes are stained with gentian violet and eosin. They are then counted on the Thoma-Zeiss counting-stage as modified by Zappert; this has nine times the area of the form ordinarily used. In practice this method is very disappointing, as the solution of the red corpuscles is either carried too far or not far enough. Ewing also makes his differential counts with the haemocytometer, using six-per-cent. salt solution tinged with gentian violet, and a dilution of 1-100. The writer has not been able to make satisfactory differential counts in this way. The only forms to be differentiated are large and small leucocytes and eosinophiles. The nuclei of the polynuclear forms are often contracted into a ball and are very hard to distinguish from the true mononuclear forms, while the differentiation of a large lymphocyte and a moderate-sized mononuclear is impossible. In the following tables the leucocytes are grouped under four heads: (P) So-called polynuclears—those forms with polymorphous nuclei and neutrophilic protoplasm, or rather neutrophilic granules in the protoplasm. A short description of these granules will be given later. (L) Large and medium-sized mononuclear forms, and the so-called transition forms, with incurved nuclei. The true sign of transition is probably the appearance of granules in the protoplasm of these cells. (S) Small mononuclear forms and lymphocytes. These forms are distinct, but their differentiation is not always possible, so that they are grouped together. (E) Eosinophiles—cells with polymorphous nuclei and coarse refractive granules which show an especial affinity for eosin and other acid stains.

For the sake of brevity the above letters (P, L, S, and E) are used at the heads of the columns showing per cent. of the various forms in the different tables.

TABLE I.—CASES OF DIPHTHERIA TREATED WITHOUT ANTITOXIN.

Remarks on Table I.—In the seven cases tabulated above the patients were all seen at their homes. The treatment was of the simplest description; in all the cases but one it consisted of a tonic of tr. ferri chlor. and strychnine, and when the age permitted a simple gargle. As previously stated, all the cases were apparently mild when first seen, but three out of the seven became quite severe. In five cases there was a distinct fall in the number of the red corpuscles per cubic millimetre. The two cases showing no fall were both very mild, one (VII.) showing no membrane at any time. The diminution in the other cases ranged between 470,000 by the third day (II.) and 2,042,000 by the sixth day (I.). A word may be inserted here as to the limitations of the Thoma-Zeiss instrument. If used by different observers, especially if they are not using it constantly and as a matter of routine the results may vary widely. Under the most favourable circumstances, when the various stages are all carried through by the same person and that person is thoroughly skilled in the use of the instrument, the limit of error may be markedly reduced, but it has always to be taken into account. In the case of the red corpuscles we should consider two counts within 200,000 of each other as practically the same. It is more difficult to determine the limit of error as regards the leucocytes. In the present series of observations it has been put at three thousand. Another question to be considered is what constitutes the normal number of the corpuscles, white and red. The personal equation enters into the question and each observer should determine his own normal standard. It is therefore enough to say that any number below 10,000 per cubic millimetre has been taken for the normal number of leucocytes and above 5,000,000 per cubic millimetre for the red corpuscles. The high count of the red corpuscles in some of the cases here reported is rather surprising, and it is possible that the normal for infants has been set too low. In these seven cases the diminution in number of the red corpuscles would seem to be directly proportionate to the severity of the case, as inspection of the table will show. As a rule, no marked diminution could be made out until after the third or fourth day; possibly corresponding to the production of the toxins and their entrance in quantity into the blood. In the four severe cases the number of the red corpuscles had not returned to normal when observation of them ceased. In Case II., a mild one, the number of the red corpuscles returned to normal in about ten days; in Case V. there was no fall, and Case VII. exhibited a steady rise from the beginning of observation.

Stained specimens were examined for evidences of degeneration or destruction of the red corpuscles. So far as our present knowledge of the subject goes, the following are the signs of such changes.

1. Diminution in number.
2. Variations from the normal in shape (poikilocytosis).
3. Variations from the normal in size (schizocytosis).
4. The presence of free pigment in the blood (melanæmia).
5. Variations from the normal in staining-reaction.
6. Presence of nucleated red corpuscles.

The last-mentioned sign (6) is truly an evidence of regeneration, but so far as is known, occurs only where such regeneration is secondary to preceding degeneration. (Exception is made of leukaemia and of the blood of very young children.)

The blood in severe secondary and pernicious anæmia always shows the presence of red corpuscles which, when stained with the triple stain, take on a violet instead of an orange tint. This is due to a loss of affinity for the acid components of the stain (acid

fuchsin and orange green) and an increased affinity for its basic component (methyl green). In a word they are neutrophilic; *i.e.*, take up a combination of the three stains, and from this fact have received the name "polychromatophilic" red corpuscles. The protoplasm of almost all of the giant nucleated red corpuscles seen in pernicious anæmia show this staining-reaction, as do also a smaller number of the ordinary nucleated red corpuscles. For this reason it is disputed whether this phenomenon is degenerative or regenerative in character. For our purpose it is enough to know that it always accompanies degeneration. To bring it out distinctly, the specimens should be heated for only one hour at 120° C., and the stain must contain a relatively small proportion of acid fuchsin.

Changes in shape (2) and in size (3) are rarely observed unless the anæmia be quite marked, 3,000,000 per cubic millimetre or under. The writer has never observed the presence in the blood of what he could convince himself was free pigment. It has been stated to occur in cases of rapid destruction of the red corpuscles, as in pernicious malarial fever for instance.

In the specimens from the seven cases of diphtheria above tabulated, no poikilocytosis (2), schizocytosis (3), melanæmia, nor the presence of nucleated red corpuscles (6) were noted. But in Cases III., IV., VI., and VII., there was apparently an increase in the number of the polychromatophilic red corpuscles. The word "increase" is used because these corpuscles are occasionally seen in normal blood. This phenomenon is merely confirmatory, and must be associated with more definite evidence of degeneration, such as a decided diminution in number of the red corpuscles, in order to be of value.

In all the severe cases a leucocytosis was present, ranging from 34,000 per cubic millimetre to normal. Beyond the fact that the severe cases showed the greatest degree of leucocytosis, no correspondence could be established either with the temperature or with the pulse. Temperature and pulse have been omitted from all the tables, as taking up too much space. In all the cases the leucocytosis gradually decreased, except in Case IV., which was not followed throughout—the number of the leucocytes reaching normal in from eight to fourteen days. Differential counts of the leucocytes in stained specimens showed the increase to be mainly in the polynuclear forms, their per cent. ranging between 88.2 and sixty-eight per cent. The large mononuclear forms seemed to be somewhat increased in number in some of the cases, but as they vary so widely in normal blood (two to twelve per cent.), no definite change can be said to have taken place in them. But the transitional forms between the polynuclear and the large mononuclear forms, which have been grouped with the latter, were seen much more frequently than in normal blood. The small mononuclear forms varied widely, but, as a rule, were decreased in number, in one case falling as low as four per cent. An increase of the lymphocytes to thirty or thirty-five per cent., as noted by Morse and Ewing, may be termed a lymphocytosis, but is not an evidence of any pathological condition, as the writer has observed thirty-two, thirty-three, and thirty-five per cent. of lymphocytes in perfectly healthy individuals. In health an increase to thirty per cent. is certainly much more common than a fall to ten per cent. The increase in the polynuclear forms was, as a rule, directly proportionate to the increase in the total number of the leucocytes. The stained specimens were also examined with reference to the staining properties of the nuclei, variations in size of the polynuclears, and variations from the normal in the granulations of the several forms. Nothing abnormal could be made out. This question is discussed more fully in the remarks on the cases treated with antitoxin.

The hæmoglobin of the red corpuscles shows about the same changes as in all the acute infectious diseases. It falls coincidentally with the number of red corpuscles, begins to rise at the same time that they do, but rises much more slowly, not reaching normal until some time after the corpuscles. Thus, in only two of our cases did the hæmoglobin return to its original figures; one case (V.) being very mild, and the other (VII.) being anæmic when first seen and exhibiting a steady rise in corpuscles and hæmoglobin from the beginning of observation. The hæmoglobin, however, had only reached seventy-six per cent. at the time of the last observation.

Remarks on Table II.—Of the cases cited twenty-three were followed throughout and six were examined only once. They will be called the "complete" and "incomplete" cases, respectively. Let us take up first the complete cases (I. to XVIII. and XXV. to XXIX.). In six of the twenty-three cases a diminution in number of the red corpuscles was noted. In Cases VI., XXV., and XXIX. there were falls of 241,000, 368,000, and 384,000 per cubic millimetre, respectively. In Case IV. there was no fall until the eleventh day of the disease, when broncho-pneumonia set in, the patient dying on the seventeenth day. A fall of 1,000,000 was noted in this case. In Cases IX.
